Table 1 Numbers of common nematode infections in humans worldwide

Species of Nematode	Numbers Infected	Distribution
<i>Ancylostoma duodenale</i> and <i>Necator americanus</i>	1,298,000,000	World-wide
<i>Ascaris lumbricoides</i>	1,472,000,000	World-wide
<i>Brugia maylayi</i> and <i>B. timori</i>	13,000,000	South Pacific, SE. Asia, India
<i>Dracunculus medinensis</i>	80,000	Sub-Saharan Africa and Yemen
<i>Loa loa</i>	13,000,000	West and Central Sub-Saharan Africa and Yemen
<i>Onchocerca volvulus</i>	17,660,000	Central and South America and Sub-Saharan Africa
<i>Strongyloides stercoralis</i>	70,000,000	Temperate regions
<i>Trichuris trichiura</i>	1,049,000,000	World-wide
<i>Enterobius vermicularis</i>	400,000,000	Temperate regions

that water exists in a liquid state even for short periods of time annually.

Diversity of Habitats and Distribution

General

The most obvious ecological character that defines habitats for members of the phylum Nemata is that they all are aquatic animals – to move, live, eat, and reproduce, nematodes must exist in an aqueous environment. This environment includes soils, muds, sands, plants, and animals. They can be found living in soils with moisture contents as low as 5–10%, but in the majority of these cases, the nemas are associated with the roots of plants. It is evident that the environment in which nematodes live constrains their ultimate size. Soil dwelling species live in the water film of the interstices of soil particles. Nematodes, must live and carry out all functions of life in these spaces, thus free-living, or plant-parasitic soil-dwelling forms are usually extremely small. Morphological diversification of nematodes can operate only within the constraints of their life-history parameters, and thus, evolutionary pathways for nematodes living in an interstitial – soil or sediment/sand environment are limited. Thus these forms have limited abilities to diversify into the nonaquatic regions of the earth, and their size is constrained by this fact.

In contrast to the small sizes of plant-parasitic, free-living marine, freshwater, or soil nematodes (some adults can be as small as (*Criconemoides*) with an adult length of around 250 μm), species that occur as parasites of animals are free from the physical constraints on their size and the bodies of species in mammals are, therefore, relatively large. In fact, the largest nematode thus far recorded is *Placentonema gigantissima* from the blue whale with a length of more than 8 meters (Maggenti, 1981). The ratio between the smallest adult nematode to the largest can be calculated as $(0.250 \text{ mm} (\textit{Criconemoides})/8,000 \text{ mm} (\textit{Placentonema}) = 0.000031$), compared to the ratio between a shrew and a blue whale $(50 \text{ mm}/24,4000 \text{ mm} = 0.12)$, indicating that the size differences in nematodes are three orders of magnitude greater than the mammals.

In the marine-benthic environment Lamshead (1993) has estimated (based on transect data from deep sea benthic samples) that there may be as many as 100 million species of marine infaunal nematodes. As exorbitant as that estimate seems, deep-sea nematodes have been show to be extremely rich in species diversity. One marine sediment sample from the east-Pacific benthos was reported to contain 148 species from a total of only 216 individual specimens examined (Lamshead 1993). At the present time the true extent of species diversity in the marine benthos can only be imagined because fewer than 20 studies of nematode community structure from marine-benthic habitats have been reported (Boucher and Lamshead, 1995). Relatively recent data from Boucher and Lamshead, 1995 shows that in marine environments the highest diversity in nematodes occurs in abyssal benthic sediments.

We now know that great numbers of individuals and species of nematodes live in sediments on the ocean floor

distributed from the intertidal continental margins to the benthos of the abyssal zones, even though these marine habitats remain unexplored. Nematodes occur in tissues and organs of all species of vertebrates that have been studied and some, such as *Physaloptera* spp. live, feed, and reproduce in the strongest stomach acids of mammals, birds, and reptiles. Dessicated specimens from both the Arctic and Antarctic have been rehydrated to form viable colonies and living nematodes have been found in the limited meltwater in some of the dry-valleys of Antarctica, an area that is probably one of the most extreme biotopes on the earth.

Extreme Biotopes

Some of the most extreme soil habitats on the Earth exist in the Dry-Valleys of the Antarctic where the annual mean air temperature is -20°C , and soil temperatures at a 5 cm depth for the two “summer months” range from -2.7° to 15.9°C . In this area, no vascular plants grow and mosses and lichens are rare; this is the only terrestrial soil-system known where nematodes are the final consumers and are at the apex of the food chain (in this case it seems more of a chain than a web). Three nematode species exist in these dry soils, *Scottinema lindsayae*, a microbivore (feeding on bacteria and yeast), *Plectus antarcticus* (a bacterial feeder), and *Eudorylaimus antarcticus*, an omnivorous predator that presumably feeds on individuals of the other two species (Powers *et al.*, 1998). In another biological extreme, Death Valley in California has recorded some of the highest temperatures in North America and the soils of the valley are teeming with nematodes, many of which have been discovered to possess similar adaptive traits to those found in the cold deserts of Antarctica.

Individuals of some species of Nemata are capable of resisting extended periods of dessication, for example, 3rd stage juveniles of *Anguina tritici* have been dried for more than 20 years in a state of anhydrobiosis in which all metabolic activities are shut down (Maggenti, 1981). These nematodes have been shown to have specialized proteins that fold into stable/preserved structures as the organism dries. In this state of crypto or anhydrobiosis, individual nematodes can remain viable through incredible extremes of temperature, desiccation, hypoxia, and even synthetic nematicides designed to kill nematodes (of course the regular biochemical processes that nematicides interfere with are not operational, so the nematode does not notice this particular assault). When water again becomes available, the animal in fact comes back to life when the molecular structures rehydrate and the proteins and enzymes spring back into normal operation.

Habitat Diversity

Nematodes occupy every conceivable life-history niche. There are benthic deep-water marine forms that appear to consume mostly diatoms and others such as species of the genus *Draconema* (Figures 5(a), 6) that are mostly associated with marine algae, but it is still unclear what they actually eat. Nematodes of the genus *Dirofilaria* live in the aorta and left ventricles of canids and are transmitted by mosquitoes from dog to dog. Species of nematodes live in the hearts of sharks,

and other species occur by the thousands weighing more than one kilogram in the stomach of a pilot whale (SLG pers. obs.), and, as the human consumption of raw marine fish (ceviche and sashimi) has increased, transfer of juvenile *Anasakis*, *Teranovus*, and other anasakines from the fish intermediate host to humans is occurring more commonly and these nematodes are turning up as parasites in the stomach of humans.

Some species feed on fungi in the soil whereas others are trapped and are themselves consumed by different species of fungi. Still other nematodes like *Mononchus* (Figure 1(b)) and *Clarkus* (Figure 16) are predatory and hunt and eat other nematodes in the soil environment. Free-living bacterial feeding nematodes have been shown to be integral parts in the carbon and nitrogen cycles in healthy soils (Ferris *et al.*, 1998) and recent survey work has shown that undisturbed or natural soils in noncultivated habitats can have as many as 20 times more species than soil from similar areas that have been under cultivation (Al Banna and Gardner, 1996).

Abundance – Estimates and Facts

In addition to the large numbers of species that may occur in any given habitat, nematodes also occur in very great densities, for instance, in sheer numerical density of individuals in any given habitat, nematodes exceed even the mites and beetles combined. More than 90,000 nematodes were recorded from a single decomposing apple, and one report showed 1 cc. of marine mud contained 45 nematodes representing 19 species. Nematodes in marine estuaries occur at high numerical densities with reports of 4,420,000 m⁻² in surface mud and 527,000,000/acre in the top 3 inches of sand in the Massachusetts coast. Counts and extrapolations for relatively moist soils (10–70% moisture content) worldwide show that in the uppermost levels, nematodes occur in mind boggling abundance: 7–9 billion/acre in undisturbed sod in North China; from 800,000,000 to > 1 billion per acre (representing just 35 species), in Utah and Idaho and around 3 billion per acre in low-lying alluvial soils of Europe and other areas of North America.

How do Nematodes Affect the Biosphere?

Because of the huge numbers of nematodes that have been shown to occur in plants, animals, soils, and the benthos, there has been much speculation about the role of nematodes in basic biological processes occurring in the soils of the earth. Cobb (1914) speculated that some nematodes “are beneficial” however he also noted that this area of study of this was still in its infancy. In fact, in 2000, this area of study is still just developing and recent work has shown that nematodes can be good indicators of biodiversity (Bongers and Ferris, 1999). Gardner and Campbell (1989) showed that mammalian parasites with complex life cycles may serve as excellent indicators of areas of high biological diversity. Because of the multifarious nature of parasitic nematodes in mammals, it is expected that these kinds of species may provide biologists with additional tools for identification of areas of high biological diversity.

The fact that parasitic nematodes occur in such high prevalence and numerical densities in mammals should give us pause, there is obviously a huge energy drain on any population of mammal that we should care to analyze, and this energy drain probably causes significant decreases in the number of offspring in any given population over long periods of time.

Soils and Plants

Recent studies indicate that nematodes play a substantial role in the cycling of carbon and nitrogen in the soil environment (Bongers and Ferris, 1999) and it has been shown that the numbers of bacterial feeding nematodes increases as the bacteria increase with annual warming of the soils. In the rainforest of Cameroon, average nematode abundances of 2.04 × 10⁶/m² of rainforest soil were found indicating that these nematodes play a significant role in carbon flux (CO₂ and CH₄) in this rain forest site (Lawton *et al.*, 1996).

Nematodes occur in, on, and around the roots, bulbs, rhizomes, stems, and leaves of plants. They can cause galls in both the somatic and germinal tissues of the plants, where the nematodes can encyst, and dry, waiting for the next stage in their life cycle. There are species that are almost fully endoparasitic, exiting the plant root or stem only as juveniles. Others are fully ectoparasitic, such as species of *Xiphinema* (the vector of grape fan-leaf virus). Some species spend part of their life-cycle in a plant and part of it in the soil. As mentioned earlier, seed parasites of the genus *Anguina* may spend most of their existence as juveniles in a dried state, the nematodes rehydrating, molting and then as adults crawling up the outside of the plant during periods of high relative humidity and then laying eggs in the seed head. The seeds are consumed by the developing juveniles, and when they dry, the seed coats protect the also dried nematodes within, and are distributed through the environment as are normal seeds (Maggenti, 1981). Nematodes of the genus *Pratylenchus* use their spear to move through the roots of the plants that they infect, penetrating the plant cells with repeated jabs of their stomatal armature.

Predators, Entomopathogenic Forms, Fungal, and Bacterial Feeders

Many nematodes that are found in the soil are either predaceous forms eating other nematodes, or forms that prey on mites, or other soil macro-organisms. The more spectacular predators such as *Mononchus* and *Clarkus* have specialized buccal structures with which to puncture the cuticles of other nematodes (Figures 1(b), 16). Microbivorous fungal and bacterial feeding nematodes are also extremely abundant with species specializing in their feeding habits on bacteria, fungi, diatoms, and other microscopic organisms. Some, such as juveniles of species of the genera *Heterorhabditis* and *Steinernema* carry special bacteria for the genus *Photorhabdus* in their digestive system. The 3rd stage juveniles wait in the soil until an unwary insect passes nearby, the nematode then homes in on and penetrates the hapless insect, making its way into the hemocoel where it releases the bacteria, which proliferate, killing the host. The nematode then feeds on the

bacterial colony and reproduces in the insect, eventually again producing 3rd stage juveniles, which leave the carcass of the insect and disperse into the soil, waiting there for another insect to invade (for more specific details of the lifecycle of these entomopathogenic nematodes see [Gaugler and Kaya, 1990](#)).

Bacterial feeding forms occur in the soil in extremely high numbers. In soils that have not been disturbed, and have a good layer of organic matter, large numbers of all kinds of nematodes occur. One of the most well-known groups is the Rhabditida or the rhabditid nematodes. These forms feed on bacteria and yeasts growing in the soil, and are typically found in high numbers in moist soils with high organic content. The most famous of these forms are members of the genus *Caenorhabditis* of which the complete genome of *C. elegans* has recently been sequenced.

Aquatic and Marine Nematodes

This is an area that is wide open for future biologists. How do the trillions upon trillions of individuals and the millions of species that occur in the oceans really affect the biosphere? Nothing is known on the subject at the present time.

How many Species of Nemata?

Estimates of Number Described

Estimates of the numbers of species of nematodes that are known (i.e., described species) vary widely. However, in 1819, Rudolphi summarized what was known of the nematodes and he recorded 11 genera and about 350 species. Just 115 years later in 1934, Filipjev reported that 4601 species of nematodes had been described with about half free-living and the other half parasitic. By 1950, Libbie Hyman estimated that approximately 9000 species were described (based on her analysis of the Zoological record with descriptions being recorded at a rate of about 200 new species being described per year). In 1981, Maggenti's summary showed around 15,000 described species. The author's analysis from counting additions to the Zoological Record shows that in a 5 year period from 1992 to 1996 numbers of descriptions were relatively stable with approximately 776 new species described (average of approximately 155 descriptions per year). From 1996 to 1998 the numbers of descriptions decreased to 118 per year, most likely due to the continued retirement and expiration of taxonomists.

How Many Species of Vertebrate Parasitic Nematodes Exist?

All species of vertebrates examined thus far serve as hosts for at least one species of parasitic nematode. Some mammalian hosts harbor many species of nematodes that are distributed through several orders and families. Some of these nematodes are highly host-specific, surviving and reproducing successfully only in host individuals comprising a single species or perhaps a closely related group of species. Other nematodes show less specificity, being much more likely to jump from one

suitable vertebrate host to another during opportune times during their life-history ([Brant and Gardner, 2000](#)).

Within a host, many different types of habitats may be occupied by nematodes. As a species, *Homo sapiens* harbors around 35 species of host-specific parasitic nematodes ([Chitwood and Chitwood, 1977](#)). To illustrate the diversity of habitats in a single animal host, humans will be used as an example. In a human, nematodes can occur as juveniles in muscle tissues, usually smooth muscle like the diaphragm or the tongue (*Trichinella*), in the mucosa of the intestine (*Strongyloides*), as migrating forms in blood, and lungs (*Ascaris*), in blood or lymph as microfilariae (Filarioids of humans), as adults in the small and large intestines (*Ancylostoma*, *Necator*, *Ascaris*), as adults in mesenteries and subcutaneous tissues (*Onchocerca*, *Loa*, *Wuchereria*) and *Enterobius* in the large intestine and cecum.

Cobb was well acquainted with animal parasitic nematodes, and his familiarity with host-specificity in the Nemata led him to estimate that as early as 1914, well over 80,000 species of nematodes would eventually be found parasitizing vertebrates alone. Similar estimates could be derived for parasites of invertebrates and plants resulting in totals of free-living and parasitic species numbers far in excess of the approximately 27,000 species of nematodes known today.

Cobb (1914) stated "There must be hundreds of thousands of species of nematodes. Of this vast number only a very few thousand have been investigated, and of these, comparatively few with any degree of thoroughness."

Present estimates are that only approximately 14,000–16,000 species of parasitic nematodes have been described from all taxa of slightly more than 48,000 currently recognized species of vertebrates. In addition, many species of wild mammals each harbor more than two host-specific species of nematode so the above estimate of 8900 species of nematodes only from mammals can be considered very low.

As of this writing, the natural history, development, and transmission parameters of only around 561 species are known ([Anderson, 1992](#)). As parasites of only vertebrates, [Anderson \(1992\)](#) estimated that there were about 2300 described genera distributed among 256 families comprising about 33% of all nematode genera known. This percentage is approximately equal to the percentage of genera of Nemata presently known in marine and freshwater habitats. It is agreed by most workers that this bias is due to the larger number of parasitologists working on selected groups of Nemata relative to the number of specialists working on the free-living marine and freshwater forms.

If each of the approximately 4450 known species of mammals were infected with only two species of host-specific nematodes, we would expect to find a minimum of 8900 species of parasitic nematodes only in the Class Mammalia.

Pinworms, nematodes of the Order Rhabditida Superfamily Oxyuroidea ([Figure 1](#)) show high levels of host specificity and it is well-known that almost all species of rodents and primates have one species-specific pinworm, (for instance, *Homo sapiens* harbors *Enterobius vermicularis*). Both recent and historical studies have shown that pinworm nematodes exhibit high levels of coevolution, i.e., concomitant host-parasite

speciation (and host-specificity) with their primate and rodent hosts (Hugot, 1999). At the present time, slightly more than 716 species of Oxyuroidea have been described with the vertebrates hosting about 496 species and invertebrates about 217 species. The greatest diversity in the Oxyuroidea to be found in the future is expected to come from examination of the Arthropoda especially beetles, cockroaches (4000 species described and more than 20–30,000 expected to be found) and millipedes (17,000 species described and more than 60,000 species expected to be found). This gives huge numbers of pinworms occurring just in the cockroaches and the millipedes if each species harbors its own species of pinworm. At least two species of pinworms (genus *Thylastoma*) occur in laboratory colonies of *Periplaneta americana* and more are expected to be found in free-living populations (J. P. Hugot, personal communication).

When adequate surveys are completed, large numbers of species of Oxyuroidea are also expected to be described from Neotropical rodents of the family Muridae. Up to the present time, only around seven species of pinworms have been described from Neotropical murids and these rodents potentially host from 400 to 800 undescribed species of Oxyuroidea, (given that only one to two new species of Oxyuroid nematode is found in each species of rodent examined). J. P. Hugot, personal communication.

Recent comparative studies in the Oxyuroidea of rodents shows that the larger the body-size of the rodent, the larger the body size of oxyurid nematodes that it harbors (Morand, *et al.*, 1996).

Comparative Nematode Diversity of New World Subterranean Rodents Geomyidae

Papers on nematode parasites from rodents of the Nearctic family Geomyidae covering the dates from 1857 to the present were reviewed. Combined with field-collected specimens from the early 1970s up to the present time, the author discovered that six of the approximately 11 nematode parasites reported from pocket gophers in North America, are host specific to only the Geomyidae (Table 2).

Of members of the vertebrate Class Mammalia, one of the most complete sets of nematode parasite data exists for rodents of the family Geomyidae. Of the approximately 35 known species of pocket gophers (Wilson and Reeder, 1993), at the present time only 15 species have been surveyed for parasitic nematodes. From those 15 species, six species of

nematodes are known to be host-specific only to geomyids. Some nematodes such as the strongylid *Ransomus rodentorum* and the heligmosomid *Heligmosomoides thomomyos* and filarioids of the genus *Litomosoides* have been reported from more than one species of gopher, other nematode species such as *Vexillata vexillata* occur only in gophers of the tribe Thomomyini (genus *Thomomys*) but do not appear to be host-species specific.

These mammals occur in an extremely wide and ecologically variable geographic area (from southern Manitoba and British Columbia south to extreme northern Colombia) therefore, there may be many more undescribed or undetected species of nematodes in these hosts than this analysis provides. In addition, no studies on genetic diversity of nematodes (or any endoparasites) in these rodents have been published, therefore, levels of genetic variation in these nematodes are unknown and the true genetic diversity that exists will probably cause an increase in the number of nematode species that are recognized.

There is little if any evidence of phylogenetic coevolution of the nematode parasites and their pocket gopher hosts. However, all species listed are specific to species of the family Geomyidae and both *Litomosoides* and *Vexillata* appear to exhibit some level of phylogenetic host specificity with two closely related North American species of *Litomosoides* being found only in geomyids (Brant and Gardner, 2000) and species of *Vexillata* occurring more generally in members of the Geomyoidea.

Nematodes of Tuco Tuco's (Ctenomyidae)

A review of the nematode parasites occurring in Neotropical rodents of the genus *Ctenomys* indicates a considerably more depauperate fauna of nematodes as compared with the nearctic Geomyidae (Table 3). Data collected from 1984 up to the present time indicate that nematodes of the genera *Trichuris* and *Paraspidodera* have cospeciatiated with their hosts and exhibit different levels of phylogenetic congruence relative to their hosts. In addition, nematodes of the trichostrongyloid (O. Strongylida) genus *Pudica* were encountered only two times from the same species of *Ctenomys* in one locality (from a sample of more than 500 individuals and more than six species of hosts examined). The occurrence of *A. caninum* in *Ctenomys* appears to be a capture, as it only occurred in areas

Table 2

Nematode species	Classification and Location in Host
<i>Trichuris fossor</i>	Sub-Phylum Adenophorea Cecum and large intestine
<i>Ransomus rodentorum</i>	Sub-Phylum Secernentea Cecum/small intestine
<i>Vexillata vexillata</i>	Duodenum
<i>Vexillata convoluta</i>	Duodenum
<i>Heligmosomoides thomomyos</i>	Duodenum
<i>Litomosoides thomomydis</i>	Mesenteries
<i>Litomosoides westi</i>	Mesenteries

Table 3

Nematode species	Classification
<i>Trichuris</i> (> 3 spp.)	Sub-Phylum Adenophorea Cecum and large intestine
<i>Ancylostoma caninum</i> (host capture in synanthropic species of rodents?)	Sub-Phylum Secernentea Duodenum
<i>Pudica</i> sp. Host capture from Muroid rodents.	Duodenum
<i>Litomosoides</i> (2 spp.)	Peritoneal cavity and mesenteries
<i>Paraspidodera</i> (> 6 spp.)	Cecum and large intestine

where dogs, humans, and ctenomyids lived in relatively close proximity (banana fields in lowland Santa Cruz, Bolivia).

Although most of the pocket gophers examined carefully generally harbor from one to several species of nematodes in the small intestine, very few nematodes are found in samples of tuco-tucos. Even though the genus *Ctenomys* contains almost 40 species, comparatively few species of nematodes have been described or reported from them. This lack of parasites in a wide-open group of mammals might be a result of rapid speciation in the mammal group with parasites failing to keep up with the speciation rate of the mammals themselves and actually losing parasites through time; there is some evidence that the ctenomyids have speciated rapidly in their history (Lessa and Cook, 1998). The lack of a diverse fauna of nematodes in these mammals could also be due to historical accident whereby the ancestor of the ctenomyids had a low diversity of nematode parasites (for whatever reason) thus giving rise to a phylogenetic lineage of mammals lacking a diverse fauna of parasites. But why have they not picked up more parasitic nematodes from other syntopic species of mammals?

There is some evidence of host-switching in nematodes of the genus *Litosomoides* in that two species occur in *Ctenomys opimus* in high-altitude Western Bolivia, but these nematodes have not been reported from any other species of *Ctenomys* from throughout the Neotropics. Superficially this indicates a host-capture event from some other lineage of mammals (Brant and Gardner, 2000). Another example is the fact that nematodes of the genus *Pudica* found in *Ctenomys* have diverse relatives in other species of muroid rodents in South America but none in ctenomyids, leading to the conclusion that most are now found in the tucos because of host-switching events, and not phylogenetic coevolution.

Nematodes of the genus *Paraspidodera* are found only in Hystriognath rodents in the Neotropical Region and these nematodes appear to have had a long historical, coevolutionary association with ctenomyids, showing varying levels of both cospeciation and host-switching. The adenophorean whip worm genus *Trichuris* occurs in many diverse groups of rodents in the neotropics and at the present time, no analyses have been done to examine the levels of coevolution with ctenomyids.

The multifarious nature of nematode diversity in subterranean mammals in the Nearctic and Neotropical Regions requires at the minimum that phylogenetic hypotheses for each group of mammals and their nematodes be developed and then each host-group can be compared with each parasite-group. Much more detailed work needs to be paid to collecting parasites from some of the unknown species of *Ctenomys* throughout the Neotropics. The same can be said about the level of knowledge of parasitic nematodes in the Geomyidae in the northern Neotropics and southern Nearctic regions.

Molecular Diversity in the Nemata

Several molecules have been used to begin to assess phylogenetic and genetic diversity within the Nemata and the number of investigations using molecular methods to try to

quantify the diversity of the nematodes is rapidly increasing (Dorris *et al.*, 1999; Blaxter *et al.*, 1998; Al-Banna *et al.*, 1997; Nielsen, 1996). However, because of the extremely large number of species that may exist, examination of levels of molecular or genetic diversity in representatives of the group as a whole can be said as just the beginning even though massive amounts of molecular data on nematodes are now literally pouring into the literature stream. The summary papers by Blaxter *et al.* (1998); Dorris *et al.* (1999); Meldal, *et al.*, 2007; Holterman *et al.* (2006); Van Megan *et al.* (2009); and Bik *et al.* (2010) indicate the utility and power of estimating the molecular-phylogenetic relationships among the Nemata using ribosomal DNA and other molecular sequence data. Initial studies of the molecular diversity within and among several lineages of the Strongylida show that the genetic diversity among these taxa is relatively low (Chilton *et al.*, 1997). From these works, it is clear that molecular phylogenies will provide robust tests of the hypotheses of morphological relationships among the Nemata. As more regions of DNA are used to examine the relationships among the nematodes, we expect additional clarification of both the deep phylogenetic branches (Bik *et al.*, 2010) that are at present relatively obscure in the molecular phylogeny of the Nemata and the more rapidly evolving branch tips that represent extant species with valuable genetic information

Relationships to other Animal Groups

A recent analysis grouped the nematodes, gastrotrichs, priapulids, kinorhynchs, and the loriciferans into a group (superphylum) called the Cycloneuralia (Figure 26) based on the circular shape of the brains in these groups (Nielsen *et al.*, 1996). The aforementioned study and at least one other (Zrzavy, 1998) using 18s rDNA sequences showed that the Nemata share a common ancestor with members of the phylum Nematomorpha but there was a shuffling of the other groups out of the "Cycloneuralia" (Figure 27).

Figure 26 Phylogenetic tree showing the relationships of the Nemata to the rest of the Cycloneuralia.

Figure 27 Phylogenetic tree showing the relationship of the Nemata to the rest of the Animalia.

Figure 28 Phylogenetic tree of the Bilateria showing the sister group of the Nemata to be members of the phylum Tardigrada or the moss bears.

More recently, Lartillot and Philippe (2008) presented a molecular phylogeny of the Bilateria where they show the Nemata as sharing a most recent common ancestor with members of the phylum Tardigrada and are close to the phylum Arthropoda in their final tree (Figure 28).

As mentioned above, nematodes are soft-bodied and mostly very small organisms, any larger forms that existed in prehistory were probably parasites of vertebrates, however, these left no fossil traces. The only fossil nematodes that are known are insect parasitic or plant parasitic forms that occur very rarely in amber inclusions, but these are also not very old. Because there are no fossil records of nematodes of Cambrian or Precambrian ages, estimates of the age of the Nemata have been only speculation up to the present time and without fossils; it is difficult to calibrate molecular clocks for the nematodes. However, through application of various models of molecular evolution and molecular clock theory, estimates

of the time of divergence of the nematodes from the rest of the animal groups appear to be approximately 1177–1179 million years (Wang *et al.*, 1999) (this study showed a basal origin of the nematodes on a phylogenetic tree, in contrast to the relatively derived placement in the analyses shown in Figures 26–28).

Most authors consider that nematodes arose from a Marine ancestor. The tri-radiate esophagus and the tubular body indicate a possible primarily sedentary existence with the posterior end attached to the substrate and the anterior end freely encountering the marine environment from all sides, thus the secondarily derived somewhat radial symmetry (Maggenti, personal communication).

Classification and Groups of the Nemata

Above the level of the order, confusion reigns relative to the classification and systematic arrangement of the nematodes. Maggenti (1991) is usually followed in this regard and his analyses followed corroborated historical analyses in recognizing the two main sub-phyla: the Secernentea and the Adenophorea. Recent work shows that these groups are substantiated both in morphological and molecular analyses although competing phylogenetic hypotheses and associated classifications have also relatively recently been proposed (Dorris *et al.*, 1999; Blaxter *et al.*, 1998; Adamson, 1989). Even more recent work by Meldal *et al.* (2007); Holterman *et al.* (2006); Van Megen *et al.* (2009) and Bik *et al.* (2010) have provided some larger scale analyses of the Nemata using sequencing of ribosomal DNA and other conserved genes.

A systematic treatment of the nematodes was recently undertaken by Hodda (2007) where he reviews the systematics of the group and proposes a classification that incorporates molecular, developmental, and morphological advances. He reviews the classification of the Nemata as a phylum (although he uses Nematoda as the name). Here the author would like to point out that Maggenti (1981, 1991a, and 1991b) used Nemata as the name for the phylum as he often pointed out that “Nematoda” is a class level name left over from the old classification when nematodes were considered a class in the phylum Aschelminthes. If the nematodes were considered a class under a different phylum name, then Class Nematoda would be appropriate, as it is, Phylum Nemata is more correct (A.R. Maggenti, personal communication).

Since 1949, at least eight authors have provided classifications for members of the phylum Nemata (Malakhov, 1994; Brooks and McLennan, 1993; Maggenti, 1991). Of these, the classifications of Maggenti (1981; 1991) have proven to be the most useful summary of all nematodes (free-living, and parasitic); however, phylogenetic hypotheses have recently been proposed based on both molecular and morphological characteristics. This does not necessarily mean that because a phylogeny has been proposed that a classification from that phylogenetic tree will result (Maggenti, 1991a and Brooks and McLennan, 1993).

At this point in time, the synthetic classification proposed by Hodda (2007), which takes the arrangement down to the level of the family, appears to be the most easily useable and informative new classification. He presents the groups in a

table format, and as noted above, uses information from many different fields of study of the Nemata to generate the classification. One of his goals was to minimize the changes in taxonomic rank of well established groups to achieve stability and he generally follows the use of superorders (e.g., Maggenti, 1991).

Future Knowledge of Nematodes

The author hopes that this summary treatment provides readers with sufficient knowledge to allow more in-depth research on nematodes. The group is so large, and so ecologically, morphologically, and phylogenetically diverse that to attempt to discuss the diversity of the group in such an abbreviated way is practically futile at best. N. A. Cobb (1914) stated this clearly on the last page of his famous "Nematodes and Their Relationships" (pp. 490).

"The foregoing fragmentary sketch may indicate to the student, as well as to the general reader, the vast number of nematodes that exist, the enormous variety of their forms, and the intricate and important relationships they bear to mankind and the rest of creation."

As more data on distribution and function of nematodes throughout the biosphere are obtained, the importance of this group of worms will surely be realized. We are just beginning to explore the oceans, and we are probably losing more species of nematodes from rainforest clearing than will ever be ultimately found, described, and classified.

The author hopes that mankind will generate more interest in the microscopic world of the Nemata, and that this section will provoke the reader into action and disprove what Van Leeuwenhoek stated about his fellow man on 28 September, 1715 in which he said: "...And over and above all, most men are not curious to know: nay, some even make no bones about saying, What does it matter whether we know this or not?" (Dobel, 1932; pp. 324–325).

Acknowledgments

Special thanks to the staff and students of the Manter Laboratory. Also thanks to Sue, Grant, and Clark Gardner for their support during this work.

Glossary

Acetabulum Ventral sucker used for attachment and locomotion in digeneans.

Acoelomate Lacking a body cavity; see parenchyma.

Cercomer Posterior parenchymous or muscular extension of body; homology among groups is controversial; some view both the hook-bearing regions of monogeneans and some larval cestodes to be modifications of the cercomer.

Cirrus Male intromittent copulatory organ consisting of distal, invaginable portion of ejaculatory duct that is evaginated (by turning inside out) through the genital pore during copulation; may or may not be armed with spines, microtriches, etc.; see penis.

Cortex The outermost region of parenchyma in taxa in which two distinct regions are present; inner boundary often marked by conspicuous circular muscle fibers; see medulla.

Duogland adhesive system Combination of a cement, a viscid gland producing adhesive material, and a releasing gland; usually associated with cells of ventral epidermis; provides temporary adhesion to the substrate for many interstitial flatworm species.

Gonochoristic Individual organisms exhibit only one of two sexes.

Haptor The posterior attachment organ of monogeneans.

Hermaphroditic Individual organisms exhibit both sexes.

Medulla The innermost region of parenchyma in taxa in which two distinct regions are present; outer boundary often marked by conspicuous circular muscle fibers; see cortex.

Microtrix A specialized surface extension of the neodermis of cestodes, characterized by an electron-dense cap composed of numerous cap tubules separated from a core of distal cytoplasm by a baseplate (plural microtriches); aid in attachment and possibly absorption of nutrients.

Monozoic Possessing only a single set of reproductive organs; see polyzoic.

Neodermis A syncytial, nonciliated epidermis with cell bodies and nuclei (often referred to as cytons or pericaryon) laying below other body wall elements; unique to the Neodermata; completely replaces epidermis, usually at metamorphosis when larva encounters the first host.

Parenchyma The connective tissue between cells of ectoderm and endoderm layers that fills spaces among organ systems; as platyhelminths are acoelomates, the space among internal organs is completely filled with parenchyma.

Penis Male intromittent copulatory organ consisting of a muscular, often papilliform, retractable structure that is protruded (without turning inside out) through the genital pore during copulation; may or may not be armed with spines, etc.; see cirrus.

Polyzoic Possessing multiple serial sets of reproductive organs; condition found in most cestode orders.

Proglottid Compartmentalized regions of cestode body; each proglottid contains one or more sets of reproductive organs; not homologous with segments of coelomates.

Rhabdite A rod-shaped, proteinaceous secretory product found in the epidermis of most free-living platyhelminths; known functions include mucus production for ciliary gliding, cocoon formation, prey capture, and predator repulsion.

Scolex Attachment organ in adult eucestodes; often bearing suckers, loculi, or hooks.

Statocyst Static sense organ in which the movement of a statolith is detected, thereby indicating an animal's orientation.

Strobila The portion of the body of cestodes exhibiting serial repetition of proglottids.

The Phylum Platyhelminthes is presently considered to contain approximately 30,000 species, although that number is likely to be a gross underestimate. These animals are usually bilaterally symmetrical, many are dorsoventrally flattened; they generally lack a body cavity and most are hermaphroditic. None of these features, however, is unique to this phylum, and thus, none can be counted on for the definitive recognition of membership in the group. That is not to say the phylum does not represent a natural assemblage of taxa. Molecular analyses support its monophyly and the platyhelminths appear to be unique in their possession of protonephridial cilia that lack accessory centrioles. Unfortunately, the latter feature can be

observed only with transmission electron microscopy and thus it is not especially convenient for the casual identification of platyhelminths. In many cases, it is more useful to turn to the rather distinctive features that characterize the individual platyhelminth subgroups.

Because they lack a protective outer body covering, water figures prominently in the lives of the platyhelminths, and indeed, the majority of species are found in moist or aquatic environments. Marine, freshwater, and terrestrial environments have all been colonized, the latter to a lesser extent than the former two environments. The phylum includes species spanning a wide range of adult lifestyles, from those that are

free-living interstitial dwellers to those that are symbiotic with invertebrates or obligate (internal or external) parasites of vertebrates. Consequently, the group includes species ranging enormously in size (200 μm –80 m), shape, form, and occasionally color. Species that are obligate parasites of vertebrates belong to four distinctive, potentially monophyletic groups: Monogenea, Aspidogastrea, Digenea, and Cestoda. A number of these are of significant medical or veterinary importance. There exists little evidence to suggest that the remaining platyhelminths, many of which are free-living members of the meiofauna and some of which exist as either commensals or parasites of invertebrates, form a single cohesive group, although collectively they are often referred to as “turbellarians.” Present knowledge suggests that the parasitic groups are more speciose than the nonparasitic groups. However, there is no question that numerous free-living and parasitic taxa await discovery and formal description.

General Features

A glance at the defining features of each of the major platyhelminth groups reveals that the characteristics that vary most among, and even within, these groups are primarily those associated with the digestive and reproductive systems. However, in the parasitic taxa, the features associated with attachment also vary markedly. When present, the digestive system generally lacks an anus. Thus, there is no unidirectional flow of food materials through this system; in many species food enters and solid wastes exit through the oral opening. Most platyhelminths are hermaphroditic, with each individual possessing both male and female reproductive organs. Several major features of the female reproductive system are of particular importance. The female gonads of platyhelminths are either homocellular, consisting of only a single type of cell that produces both ova and vitelline material (i.e., yolk and shell precursors), or heterocellular, consisting of two cell types, one that produces ova and one that produces vitelline materials. The former configuration results in the production of endolecithal eggs thus vitelline material is incorporated directly into the cytoplasm of the ova; the latter configuration results in the production of ectolecithal eggs, as vitelline cells are packaged along with, but independent of, the zygote in the egg. Heterocellular platyhelminths usually, but not always, conduct these functions in separate organs, often possessing one, or occasionally more, ovaries that produce ova, and a vitellarium consisting of vitelline cells that produce nutritive yolk and shell precursors.

In addition, most platyhelminths possess a formalized excretory system consisting of two (rarely one or three) sets of protonephridia, which may be connected at several points throughout the body or may join at a common excretory vesicle. The nervous system and sense organs are present to a greater or lesser extent among different taxa. Specialized organs functioning in respiration and circulation are entirely lacking in many groups of platyhelminths. Thus, respiration generally occurs by means of diffusion of gases directly through the surfaces of the body, a process that is greatly facilitated by the relatively flattened nature of the platyhelminth body. The “circulation” of materials throughout the various

parts of the platyhelminth body is also accomplished by diffusion. However, a number of digeneans are known to possess a “lymphatic system” with contractile vessels and cellular inclusions that may have a circulatory function. The details of most organ systems are difficult to observe without the use of specialized staining and microscopic techniques.

One final, rather unusual feature of the platyhelminths is that the differentiated nonreproductive (somatic) cells of the body are unable to divide. Thus, mitosis does not occur in the differentiated somatic cells of platyhelminths; rather, these cells are replaced as necessary by undifferentiated stem cells located below the outer layers of the body, which undergo mitosis. This phenomenon helps to explain the remarkable regenerative abilities of certain platyhelminth groups.

Major Groups

Diversity in the platyhelminths is most effectively represented at the taxonomic rank of order (or superfamily in the digeneans). Within the phylum, this rank is relatively informative and is much more numerically manageable than lower ranks such as family or genus (i.e., there are 71 orders (or superfamilies in the case of the digeneans) versus 391 families and 3847 genera). However, it is important to recognize that traditionally, not only have taxonomists working on each of the three major groups exhibiting obligate parasitism (Digenea, Monogenea, and Cestoda) generally worked independently from one another, but they have also worked independently from the taxonomists studying the platyhelminths exhibiting more free-living life history strategies. Thus, the concepts of higher ranks, such as order, are not necessarily comparable among the major groups. For example, the 716 genera of monogeneans are currently distributed among ten orders, whereas the 1592 genera of digeneans are distributed among only three orders. Nonetheless, diagnoses are presented for orders in all groups except the digeneans, which are treated at the level of superfamily. The numbers of families and genera for each of the orders (or superfamilies in the case of the digeneans) are given in **Table 1**. This treatment reflects recent taxonomic revisions and discoveries, and thus, in addition to revised estimates of families and genera, includes two turbellarian orders, four cestode orders and eight digenean superfamilies not included in the first edition of this article. Given the lack of a recent comprehensive treatment, the numbers presented below for the monogeneans were developed in consultation with I. Whittington and D. Kritsky. The Acoela and Nemertodermatida have been removed from consideration because they are no longer considered to belong to the Platyhelminthes, rather they appear to be basal bilaterians, or possibly even early divergent deuterostomes.

For more detailed information on specific groups, readers are referred to the works of Cannon (1986), Rieger (1998), and Tyler *et al.* (2006–2010) for the non-neodermatan (i.e., free-living and invertebrate associated) groups; Yamaguti (1971); Schell (1985), and the CABI keys (Gibson *et al.*, 2002; Jones *et al.*, 2005; Bray *et al.*, 2008) for the digeneans;

Yamaguti (1963); Schell (1985) and Boeger and Kritsky (2001) for the monogeneans; and Schmidt (1986) and Khalil *et al.* (1994) for the cestodes. However, the treatments of these groups by Hyman (1951) and the five sections covering the platyhelminths in the *Traité de Zoologie* (Grassé, 1961) are classics and remain among the more comprehensive sources of detailed information on the platyhelminths. The many works of Klaus Rohde (e.g., 1997), Ulrich Ehlers (e.g., 1985), Peter Ax (e.g., 1996), and Tim Littlewood (e.g., 2006), among others, have done much to further our understanding of the morphology and phylogenetic relationships among these groups.

Discussions of diversity are most effectively organized around hypotheses of the phylogenetic relationships among the groups involved. Although many aspects of the phylogenetic relationships among the members of this phylum remain unresolved, the tree in **Figure 1** illustrates some of the aspects of these relationships for which supporting morphological and molecular data are starting to accumulate. The presentation of diversity that follows is generally organized around the topology of this tree. The non-neodermatan orders are treated in the sequence in which they appear from left to right on this tree; orders or superfamilies of each of the three major neodermatan groups are treated in alphabetical order. A more detailed treatment of the phylogenetic relationships among the various groups is provided in the section on Phylogenetic Relationships.

The authors have presented an illustration of a representative of each platyhelminth order (or superfamily for the digeneans). A consistent stippling pattern has been used throughout these figures for each different organ system so that the conditions of the major organs are readily visible and comparable among figures and among major groups. The organs represented by each stippling pattern are labeled in **Figure 9** (**Plate 1**) and **Figure 28** (**Plate 3**).

"Turbellaria"

Catenulida

See **Figure 2** (**Plate 1**). Some with tail; lamellated rhabdites absent, unlamellated rhabdoids present; duogland adhesive system absent; epidermal ciliation sparse, with cilia able to reverse beat; some with V-shaped ciliated oral furrow; brain lobed or not; statocyst often present, usually with one but occasionally with up to six statoliths and several parietal cells; mouth ventral, opening into simple pharynx; intestine in form of simple elongate sac; some lacking mouth and obtaining nutrients from endosymbionts in trophosome; protonephridial system unpaired; with single hermaphroditic gonad or separate male and female gonads; sperm aflagellated; penis present or absent, with common genital pore; vitellarium absent; eggs endolecithal; most undergo asexual multiplication *via* paratomy (subdivision of the body into multiple parts, each of which develops a head) or parthenogenesis (development of an embryo without fertilization).

Habitat: All species are free-living, primarily in freshwater, but some in marine and terrestrial environments.

Macrostomida

See **Figure 3** (**Plate 1**). Frontal glands sometimes present; some with spatulate posterior region bearing adhesive papillae; lamellated rhabdites present; duogland adhesive system present; brain not encapsulated; statocyst absent; simple pharynx present, sometimes tubular; intestine in form of simple elongate sac, sometimes with pre-oral blind sacs; with protonephridial system paired; testes compact, single or paired; sperm aflagellated; seminal vesicle present or absent; prostatic vesicle present or absent; penis present or absent; penis stylet present or absent, female pore anterior to male

Figure 1 Hypothesized phylogenetic relationships among major platyhelminth groups. State "0" should be assumed prior to point at which character is marked on tree; state "1" should be assumed if character is marked on tree but no state is given. Solid bars indicate homoplasious characters; x indicates character reversals. Topology is synthesized from various recent molecular systematic estimates of phylogeny; where there exist no morphological apomorphies there is often consistent support from molecular data.

- Accessory centriole in protonephridial flame bulb cilia: 0 = present; 1 = absent
- Protonephridial type (sensu Rhode, 1991): 0 = Type 2; 1 = Type 1; 2 = Type 3
- Protonephridial system: 0 = paired; 1 = unpaired
- Sperm flagellation: 0 = no flagellum; 1 = biflagellated
- Rhabdites: 0 = absent; 1 = present (CHECK distribution!)
- Duogland adhesive system: 0 = absent; 1 = present
- Arrangement of microtubules in sperm flagella when present: 0 = 9 + 2; 1 = 9 + '1'
- Intestinal branching: 0 = absent; 1 = extensive
- Configuration of female gonad: 0 = homocellular; 1 = heterocellular
- Eggs: 0 = endolecithal; 1 = ectolecithal
- Relationship between ovary and vitelline tissues: 0 = in same organ; 1 = in separate organs
- Flagellum of sperm cell: 0 = not incorporated into cytoplasm of sperm cell; 1 = incorporated into cytoplasm of sperm cell
- 2–12 anterior tentacles: 0 = absent; 1 = present
- Digestive system: 0 = present; 1 = absent
- Extra, embryonic intestine: 0 = absent; 1 = present
- Form of outer body layer: 0 = cellular epidermis; 1 = syncytial neodermis
- Epidermal cells: 0 = not shed by larva; 1 = shed by larva
- Haptor: 0 = absent; 1 = present
- 4 rhabdomic ocelli at some time in their lives: 0 = absent; 1 = present
- Complex life cycle: 0 = absent; 1 = present

pore; ovary single or paired; vitellarium absent; eggs endolecithal; genital pores separate or combined; ability to asexually produce zooids present or absent.

Habitat: All species are free-living in marine, brackish, or freshwater environments.

Haplopharyngida

See Figure 4 (Plate 1). With protrusible anterior proboscis not connected to digestive system; lamellated rhabdites present; duogland adhesive system present; brain enclosed in connective tissue capsule (encapsulated), bilobed; statocyst absent; mouth opens into simple muscular pharynx; intestine in form of simple elongate sac; protonephridial system paired; single testis present; sperm aflagellated; penis present, with stylet and circle of hard, straight needles; single ovary; vitellarium absent; eggs endolecithal; with single posterior/ventral pore.

Habitat: Both species free-living in marine environments.

Polycladida

See Figure 5 (Plate 1). Body oval or elongate, or thick and broad with folded margins; with (Cotylea) or without (Acotylea) pseudosucker posterior to female genital pore; anterior or nuchal (neck) tentacles present or absent; ventral prostatic-like organs present or absent; dorsal surface smooth or papillate; body margins of some with hard spines; may be multicolored with complex patterns; lamellated rhabdites present; duogland adhesive system present; statocyst absent; numerous ocelli usually present, marginal or scattered anteriorly, some arranged in one or two pairs of clusters (cerebral and tentacular), some ventral; pharynx variable in position, ruffled and vertically oriented or sometimes consisting of anteriorly directed tube, rarely consisting of multiple tubes arranged ventrally; intestine usually with numerous radiating branches, branches sometimes anastomosing, sometimes with anal pores; protonephridial system paired; testes numerous, scattered between branches of gut; sperm biflagellated, flagella not incorporated into body of sperm, $9 + '1'$ microtubule arrangement; true seminal vesicle present or absent; intromittent organ absent or in form of penis or cirrus; penis stylet present or absent; cirrus armed or not; prostatic vesicle present or absent; bursa copulatrix present or absent; some with multiple copulatory complexes; ovaries numerous, dorsal to branches of gut; Lang's vesicle (possibly for digestion of excess sperm)

opening into vagina present or absent; uterus present or absent (in form of expanded oviducts in some); vitellarium absent; eggs endolecithal; male and female gonopores usually separate (male anterior to female) but sometimes combined; some with hypodermic impregnation.

Habitat: Predominantly marine, a few in freshwater or brackish water; mostly free-living, some interstitial, some symbiotic with other invertebrates, for example, wrapped around the abdomen of hermit crabs, associated with gorgonian corals in mantle cavities of gastropod or lamellibranch molluscs, in genital bursa of ophiuroid or echinoid echinoderms; some live in association with their food, for example, in association with tunicate colonies feeding on zooids, or in association with oyster colonies feeding on oyster tissue; some seek shelter in empty shells.

“Lecithoepitheliata”

See Figure 6 (Plate 1). Some with weak posterior adhesive zone; some with pigmentation; lamellated rhabdites possibly present; duogland adhesive system present; statocyst absent; mouth anterior; pharynx variably bulbous, anterior; intestine in form of simple elongate sac; protonephridial system paired; testes compact or follicular, one or many; sperm biflagellated, flagella not incorporated into body of sperm, $9 + '1'$ microtubule arrangement; seminal vesicle present or absent; penis present, usually with stylet; muscular copulatory bulb present or absent; accessory male organ present or absent, if present opening into male atrium, prostatic vesicle present or absent; male pore opening to outside or into pharyngeal cavity; female organ single or tetrapartite, in form of heterocellular germovitelarium (vitelline-producing cells surrounding ovum-producing cells); seminal receptacle present or absent; genitointestinal canal sometimes present; female pore ventral; eggs ectolecithal (yolk not produced in oocytes). The group is likely not monophyletic.

Habitat: All species are free-living in freshwater, marine, or terrestrial environments.

Bothrioplanida

See Figure 7 (Plate 1). With posterior papillae (i.e., *Haftpapillen*); body ciliated, with two pairs of ciliated pits; statocyst absent; pharynx plicate, posteriorly directed; gut splitting laterally around pharynx and fusing again posterior to pharynx, with lateral diverticula; with one pair of protonephridium;

Plate 1 “Turbellaria” (Figures 2–15) 2. Catenulida: adult of *Retronechts* sp. 3. Macrostomida: adult of *Bradynechts* sp.; 4. Haplopharyngida: adult of *Haplopharynx* sp. 5. Polycladida: adult of *Cestoplane* sp. (Beauchamp in Grassé, 1961); 6. “Lecithoepitheliata”: adult of *Gnosenesima* sp. 7. Bothrioplanida: adult of *Bothrioplanus* sp. (Beauchamp in Grassé, 1961); 8. Proseriata: adult of *Parainvenusta englarorum* (Curini-Galletti, et al., 2010); 9. Kalyptorhynchia: adult of *Cystiplana* sp. 10. “Dalyellioida”: adult of *Syndesmis* sp. 11. Temnocephalida: adult of *Temnocephala* sp. (Baer in Grassé, 1961); 12. “Typhloplanida”: adult of *Promesostoma* sp. (Ehlers, 1974); 13. Prolecithophora: adult of *Prolecithoplana* sp. (from several literature sources); 14. Tricladida: adult of *Dugesia* sp. 15. Fecampiida: adult of *Fecampia balanicola*. Abbreviations: A, adhesive disc; AD, adhesive glands; AO, accessory male organ; B, brain; C, cirrus; CB, copulatory bulb; CGP, common genital pore; CO, copulatory organ; COB, copulatory bursa; CP, ciliated pits; E, eyespot; EV, excretory vesicle; FP, female genital pore; GC, genitointestinal canal; GD, gut diverticula; GL, gland cells; GV, germinovitelarium; I, intestine; M, mouth; MP, male genital pore; O, ovary; OC, ocellus; OGO, orogenital opening; OT, ovotestis; P, penis; PG, proboscis glands; PH, pharynx; PR, proboscis; PS, pseudosucker; PV, prostatic vesicle; RT, rhabdoid tracts; SC, statocyst; SL, statolith; SR, seminal receptacle; ST, stylet; SV, seminal vesicle; T, testis; TE, tentacle; U, uterus; UG, uterine gland; V, vitellarium; VD, vitelline duct.

testes paired, compact, possibly producing only degenerate sperm; ovaries small, paired, at distal end of vitelline duct; vitellarium follicular; with single gonopore; genitointestinal canal extending from genital atrium to posterior arm of gut.

Habitat: Single known species free-living usually in freshwater environments, occasionally terrestrial.

Proseriata

See Figure 8 (Plate 1). Epithelial nuclei insunk or not; body of some with feeble or prominent tactile bristles; body uniformly ciliated (sometimes with exception of caudal tip) or cilia restricted to ventral surfaces and head; head with or without ciliated pits; lamellated rhabdites absent; duogland adhesive system present; brain encapsulated or not; statocyst present or absent; pigmented ocelli present or absent; pharynx plicate, tubular; intestine linear or tripartite, dorsal to pharynx; protonephridial system paired or tripled, occasionally single; testes single, paired or multiple, usually follicular, rarely compact; sperm biflagellated, flagella not incorporated into body of sperm, 9 + '1' microtubule arrangement; usually with single male copulatory; occasionally with accessory (prostatoid) organ; bursa present or absent; with one pair of compact ovaries, ovary subdivided into smaller follicles consisting of oocytes surrounded by accessory cells in some; vitellarium follicular, follicles in paired lateral rows; vagina externa present or absent; genitointestinal canal usually present; eggs ectolecithal; genital pores common or separate.

Habitat: Free-living, predominantly in marine environments; a few occur in freshwater; occasionally ectocommensal on marine crustaceans.

Kalyptorhynchia

See Figure 9 (Plate 1). Body usually ciliated throughout; rarely with subepidermal spicules of crystalline calcium carbonate; rarely with anterior girdle of highly vacuolated epidermal cells; anterior sheathed proboscis usually present, divided or not, with or without hooks, gland cells, or specialized apex; lamellated rhabdites present in some; duogland adhesive system present; statocyst absent; ocelli present or absent; pharynx variable in position (anterior or posterior), bulbous, usually oriented ventrally, with or without sphincter or hard knobs, not associated with proboscis; gut usually in form of simple elongate sac; protonephridial system paired; testes single or paired, or in form of median row of follicles; sperm biflagellated, flagella not incorporated into body of sperm, 9 + '1' microtubule arrangement; internal seminal vesicle in copulatory bulb or not; copulatory organ with stylet or not; or three separately opening prostatic organs with their own spiny cirri, or one cirrus, or copulatory organ with no penial or cirrus structures; prostate vesicle incorporated in testis or not; prostate with spiny structures or not; ovary and vitellarium separated or not (ovo-vitellarium), paired or single; uterus generally present, with or without accessory piece; seminal receptacle present or absent, paired or not; bursa present or absent; eggs ectolecithal; usually one but sometimes two gonopores.

Habitat: All species free-living, primarily in marine or brackish water, several in freshwater, environments.

“Dalyellioida”

See Figure 10 (Plate 1). Lamellated rhabdites present in some; duogland adhesive system absent; cilia completely covering body, or just ventral; statocyst usually lacking; paired ocelli present or absent; mouth, pharynx, and intestine present or occasionally absent; pharynx bulbous, oriented anteriorly if present; intestine in form of simple elongate sac if present; paired protonephridial system present or occasionally absent; testes paired, compact or lobed; sperm biflagellated, flagella not incorporated into body of sperm, 9 + '1' microtubule arrangement; with or without male copulatory organ; if present male organ with or without stylet; ovary and vitellarium separate or occasionally combined; ovary single or paired, lobed; vitellarium single or paired, branched or unbranched; seminal receptacle present or absent; uterus present; copulatory bursa present or absent; single genital pore present or absent; at least one taxon is gonochoristic and sexually dimorphic (*Kronborgia*). The group is likely not monophyletic.

Habitat: Some species free-living in marine, freshwater, or terrestrial environments; many species commensal or parasitic: for example, in connective tissue of tube feet of asteroid echinoderms, in hemocoel of crabs, shrimp, amphipods, and isopods, in the mesenchyme of myzostomid annelids, in kidneys and gonoducts or mantle cavity and gut of gastropod molluscs, in stomach of lamellibranch molluscs, in mesenchyme of the turbellarian *Plagiosomum*, in either the coelom or the digestive tract of holothurioid, echinoid, or crinoid echinoderms; some also in sipunculans.

Temnocephalida

See Figure 11 (Plate 1). Usually with two to 12 anterior tentacles, tentacles usually adhesive; with posterior adhesive region, usually circular but occasionally crescentic or divided into two or more smaller regions, often pedunculate; some with lamellated rhabdites, if present restricted to anterior region of body; duogland adhesive system absent; locomotory cilia usually absent; outer body layer divided into a series of syncytial epidermal plates; statocyst absent; paired ocelli usually present; mouth terminal or ventral; pharynx tubular or bulbous, usually oriented anteriorly, sometimes reduced; intestine in form of simple sac or with weak lateral diverticula; paired protonephridial system present, usually with two lateral excretory vesicles; with one to 10 pairs of testes; sperm biflagellated, flagella not incorporated into body of sperm, 9 + '1' microtubule arrangement; male organ usually armed, usually with eversible cirrus mounted on tubular or conical shaft; ovary single; vitellarium lateral or scattered in form of large follicles over intestine; eggs ectolecithal.

Habitat: Entirely freshwater; ectocommensal, primarily on external body surfaces, gills, or lining of branchial chambers of decapod crustaceans, occasionally found on amphipods, molluscs, turtles, and hemipterans.

“Typhloplanoida”

See Figure 12 (Plate 1). Very small; anterior usually modified with prominent rhabdoid tracts or rarely with an impermanent sheathed proboscis, or with a permanent terminal invagination with proboscis glands; dermal and adenal rhabdites usually present; duogland adhesive system present; cilia uniform throughout all surfaces of body or restricted to ventral surface; brain undivided; statocyst absent; paired ocelli present or absent; tubular spinous, buccal region occasionally present; mouth usually midventral or posterior, occasionally anterior; pharynx usually ventrally oriented, plicate or bulbous; intestine in form of simple elongate sac; paired protonephridial system present; testes single or paired; sperm biflagellated, flagella not incorporated into body of sperm, $9 + '1'$ microtubule arrangement; single or paired seminal vesicles sometimes present; male system often with funnel-shaped stylet; sheathed, unarmed cirrus present; penis papilla sometimes present; ovary and vitellarium usually separate; ovary single, paired, or unpaired; vitellarium paired or a column of serially arranged follicles; usually with bursa copulatrix and seminal receptacle; vagina usually absent; eggs ectolecithal; male and female pores separate or combined, male anterior to female; common orogenital pore present or absent. The group is likely not monophyletic.

Habitat: Species known from freshwater, terrestrial, and marine environments; mostly free-living; a few known from the body surfaces of polychaete annelids.

Prolecithophora

See Figure 13 (Plate 1). With or without ciliated groove around anterior of body; anterior adhesive disc usually absent (present in Hypotrichinidae); extensive epidermal spicules present or absent; cilia uniform throughout all surfaces of body or restricted to ventral surface; brain encapsulated or not; statocyst absent; one to three pairs of ocelli present or absent; mouth anterior, midventral or posterior; with simple, plicate or weakly bulbous pharynx; intestine in form of simple elongate sac, well defined (surrounded by tunic of connective tissue) in most; paired protonephridial system present; testes, one or two, compact or diffuse; sperm biflagellated, flagella not incorporated into body of sperm, mitochondria with elaborate outer cell membrane foldings; seminal vesicle in some; male copulatory stylet rarely present; ovary and vitellarium not fully separated in some, but separated in others; ovary compact or diffuse, paired or not; vitellarium usually diffuse; accessory female openings present or not; eggs ectolecithal; male pore opening anterior to female opening but into common atrium; combined mouth and gonopore or gonopore opening separate from mouth.

Habitat: Predominantly marine, some inhabiting freshwater; free-living, or symbiotic (commensal or parasitic) on gills, on body surfaces, in mantle cavity of gastropod and lamellibranch molluscs, or on surface of small crustaceans; rarely parasitic on anal and branchial regions of fish; some of these associations may be phoretic, with the worm using the host merely for transport.

Tricladida

See Figure 14 (Plate 1). Usually large, flattened, elongate; body sometimes pigmented, terrestrial forms often colorful; some with triangular, semilunate, or pointed anterior region of body; caudal adhesive disc present or absent; lamellated rhabdites present in some; duogland adhesive system present; cilia uniform throughout all surfaces of body or restricted to ventral surface; statocyst absent; with many ocelli or one pair of ocelli (cave dwelling species lack ocelli), ocelli sometimes with distinct lens; mouth in middle or posterior half of body; pharynx plicate or tubular, posteriorly directed, usually one, occasionally more pharynges; intestine tripartite with one anterior and two posterior branches, posterior branches fused or not, diverticula sometimes present; anterior branch sometimes anterior to brain; protonephridial system paired; testes, two or many; sperm biflagellated, flagella not incorporated into body of sperm, $9 + '1'$ microtubule arrangement; seminal vesicle present or absent; male copulatory structures complex; penis usually pyriform, usually unarmed, but sometimes armed with spines or stylet; prostate organ usually absent; one pair of small ovaries usually at anterior of body, often anterior to brain; female copulatory structures variable, with or without copulatory bursa; accessory genital organs may be present in form of extra bursae each with separate pore; vitellarium follicular, extensive; genitointestinal canal sometimes present; eggs ectolecithal; gonopore usually single, rarely two or three; unique temporary embryonic pharynx (i.e., “blastomerenanarchie”) and intestine replaced by definitive pharynx during development to adult stage.

Habitat: Predominantly free-living in marine, brackish water, freshwater, or moist terrestrial environments (suborders associated with habitats); one family known only from freshwater caves; some symbiotic with other invertebrates, for example, in mantle cavity of gastropods, or gill lamellae of horseshoe crabs, or on dorsal surface of skates.

Fecampiida

See Figure 15 (Plate 1). Evenly ciliated (dorsally and ventrally), with rhabdites (without ciliated groove); pharynx variabilis, or lacking; oral-genital pore terminal (or mouth, pharynx, and intestine lacking, or with pad of epidermal cells on dorsal side of body); ovaries and vitellaria separated; ovary and testes separated or combined in ovotestis; gonopore posterior or absent; thickening of cutaneous muscles.

Habitat: Symbiotic with invertebrates such as molluscs, crustaceans, polychaetes, and occasionally teleosts.

Subphylum Neodermata

Ehlers championed the recognition of the remaining platyhelminth groups as the Neodermata because they share a unique outer body covering in the form of a neodermis, which is sometimes also referred to as a tegument (Figure 16). Neodermatans generally begin life with a single-layered, cellular, ciliated epidermis, like most of the non-neodermatan platyhelminth groups. But, as they mature this outer epidermal layer is shed and replaced with a neodermis. This

Figure 16 Neodermis of a cestode. Abbreviations: BA, basal lamina; BP, base plate; CM, circular muscle; COR, core; CPT, cap tubules; CYE, cytoplasmic extension; FIT, filithrix; LM, longitudinal muscle; SPT, spinithrix; SY, syncytium.

transformation usually occurs when the first larval stage encounters its host. The neodermis is characterized by the fact that the cytoplasm of neodermal cells is continuous throughout the surface of the animal as there are no cell membranes separating adjacent cells in this layer (i.e., it is a syncytial layer). Furthermore, the nuclei of these cells are generally located below the basal lamina and outer muscle layers of the body, in structures called cytons or pericarya. These are the nuclei of the stem cells, the cytoplasm of which grew outward to form the syncytial layer of the neodermis. The cytons are connected to the outer syncytial layer by thin cytoplasmic extensions. Furthermore, the configuration of the sperm flagella is unusual in neodermatans in that rather than remaining separate from the main sperm body, they are incorporated into the cytoplasm of the sperm body. Unlike other platyhelminths, the neodermatans are generally associated with one or more vertebrate hosts at some point in their lives.

There are four major neodermatan groups: the Monogenea (i.e., the Monopisthocotylea and Polyopisthocotylea), the Aspidogastrea and the Digenea (collectively referred to as the Trematoda), and the Cestoda. The orders of these major groups, or superfamilies in the case of the digeneans, are treated separately below.

Class Monogenea

Adult Monogenea (or Monogenoidea) are primarily external parasites of cold-blooded aquatic, or occasionally terrestrial, vertebrates. However, a few occur internally in the body cavity

or very rarely the digestive system of their hosts and one parasitizes the eyes of hippopotamuses. The majority of monogeneans possess a ciliated, free-swimming larval stage known as an oncomiracidium, although the larvae of several groups are unciliated.

Adults generally possess both anterior and posterior attachment structures. The form of the anterior attachment structure varies among groups, consisting of one or two sucker-like organs, pseudosuckers, or grooves. In some cases this region is equipped with gland cells. In the past this anterior structure has been referred to as a prohaptor. The posterior attachment structure also varies widely in morphology among taxa and its form is the primary distinction between the two subclasses of monogeneans, the monopisthocotyleans and the polyopisthocotyleans. This structure is generally now referred to as a haptor, although in the past the term opisthaptor has also been used. This structure is also present in the oncomiracidial stage. The haptor may be symmetrical or asymmetrical, may bear glands, suckers, and may be subdivided into numerous loculi. In addition, the haptor of most monogeneans is armed with a series of hardened structures greatly facilitating attachment to the host. The terminology of these structures is based to some extent on their morphology but also to a large extent on when they appear in the course of development. For example, the small hooked structures that are usually found around the periphery of the haptor of the ciliated larval stage, or oncomiracidium, and which persist into the adult stage of some monopisthocotyleans, are termed hooklets or uncinuli. The larger, more centrally located hooked structures are generally termed hamuli or anchors, depending on whether or not they are present in the

oncomiracidium. The more complex structures consisting of multiple sclerites, which are found only in polyopisthocotyleans, are termed clamps. Four rhabdomic ocelli are present in at least one stage of development. The mouth is almost always located in the anterior region of the body. Most monogeneans possess a conspicuous muscular pharynx and an intestine that is usually divided into two, or rarely one, blind caecum; the caeca are occasionally branched or anastomose posteriorly. All monogeneans are hermaphroditic. The male and female genital pores are ventral and usually combined. The number of testes ranges from one to many among different groups. Most groups possess a single ovary that varies somewhat in form from compact to double inverted U-shaped. The male intromittent organ can be a penis or a cirrus, but the exact form of this feature is not well known in some groups. The terminal genitalia are often complex. The excretory system consists of two sets of protonephridia that open separately to the outside, usually in the anterior of the body, but that may be connected at some point in the body.

Molecular work has called the monophyly of the class Monogenea into question. This is reflected in the unresolved nature of this node in the tree presented in [Figure 1](#). However, the mutual monophyly of the subclasses Monopisthocotylea and Polyopisthocotylea appears to be well supported. Members of these subclasses are relatively easy to recognize. Most conspicuously, the Polyopisthocotylea possess a haptor that is subdivided into multiple suckers or bears distinctive attachment structures known as clamps, and the Monopisthocotylea, possess a haptor that, although it may bear loculi, is undivided and, although it may bear anchors or hamuli, never bears clamps. Furthermore, unlike the monopisthocotyleans, the polyopisthocotyleans possess a genitointestinal canal such that their genital ducts open into their intestine. [Boeger and Kritsky \(2001\)](#) provide a number of additional features unique to each subclass. The interrelationships among the orders in each subclass are controversial. The orders in each Subclass are treated below in alphabetical.

To make the following diagnoses more concise, unless mentioned, it should be assumed that an order possesses the following: a posterior, discoidal, undivided, symmetrical haptor, a conspicuous muscular pharynx, a gut consisting of two blind intestinal caeca, paired testes, biflagellated sperm, flagella incorporated into body of sperm, 9+1 microtubule arrangement, a single ovary, a vitellarium that is follicular with follicles arranged in two extensive lateral fields, operculate ectolecithal eggs, and a single, ventral genital pore ([Plate 2](#)).

Subclass Monopisthocotylea

Capsalidea

See [Figure 17 \(Plate 2\)](#). Anterior end with paired petaloid head organs or paired glandular pseudosuckers; haptor sometimes subdivided by septa into central area and multiple peripheral loculi, with 14 marginal hooklets and two or four central anchors and two anterior sclerites; mouth ventral; intestinal caeca fused posteriorly, with lateral and axial diverticula; testes, two to many; sperm microtubules absent; vas deferens forming bipartite external seminal vesicle and simple

internal vesicle, or seminal vesicle absent; penis sac present or absent; penis present or absent; penis elongate, muscular, spines absent; some with cirrus; prostatic complex present; vagina present or absent; seminal receptacle present or absent; genital apertures usually combined, marginal; oviparous.

Habitat: Adults parasitic on skin or gills of marine teleosts (including remoras), or on skin or gills of elasmobranchs.

Dactylogyridea

See [Figure 18 \(Plate 2\)](#). With two or more pairs of head organs, with or without cephalic glands; posterior half of body covered with anteriorly directed cuticular spines or not; haptor with one or two pairs of anchors supported by one to four transverse bars, with or without accessory plaques, occasionally with two suckers and median terminal anchor complex, usually 14 or 16 marginal hooklets; mouth subterminal, caeca fused posteriorly or not, with lateral diverticula or not; testes usually one; sperm with one axoneme; vas deferens encircling left caecum; seminal vesicle usually present; prostatic complex present; male copulatory organ sclerotized, elongated, muscular, ovary compact, lobed or tubular; vitellarium follicular or occasionally divided into tubular lobules in form of frond-like sprays spreading in two or three lateral groups (Proto-gyrodactylidae), coextensive with intestinal caeca; seminal receptacle and vagina present or absent; oviparous; eggs oval or tetrahedral; genital aperture median or marginal.

Habitat: Adults parasitic on gills and skin of marine and freshwater, occasionally brackish water, teleosts; rarely on gills or in heart of elasmobranchs.

Gyrodactylidea

See [Figure 19 \(Plate 2\)](#). With two head organs; haptor usually with one pair of anchors often supported by dorsal and ventral transverse bars with 16 marginal hooklets; mouth ventral, intestinal caeca, one or two, usually not fused posteriorly; testis single; sperm microtubules absent; vas deferens encircling left caecum; male copulatory organ sclerotized or muscular, spines present or absent; accessory piece present; vitellarium symmetrical, near posterior part of intestinal caeca; vagina absent or present, opening ventrally near left margin of body; genital pore marginal; most species viviparous; eggs oval or tetrahedral.

Habitat: Adults parasitic on gills or skin of freshwater and marine teleosts, in stomach and intestine of amphibians, and gills and tentacles of squid; udonellids on marine crustaceans.

Lagarocotylidea

See [Figure 20 \(Plate 2\)](#). Oral sucker-like organ absent; with cephalic glands; haptor with 14 submarginal and 2 subcentral hooklets; mouth midventral; caeca not fused posteriorly, without lateral diverticula; with single U- or V-shaped testis; vas deferens encircling left caecum; seminal vesicle present; prostatic reservoir dorsal to copulatory complex; male copulatory organ sclerotized, with accessory piece; ovary compact; vitellarium consisting of two dense bilateral bands of follicles; seminal receptacle absent; vaginal pore dextro-ventral at level of genital pore; eggs without filaments; genital aperture median.

Habitat: Adults parasitic in the cloaca of salamanders.

Monocotylidea

See Figure 21 (Plate 2). With single anterior sucker or several sucker-like depressions or paired head organs (lobes) with cephalic glands; haptor aseptate or divided by septa into loculi, often with one pair of anchors, with or without marginal papillae, usually with 14 marginal hooklets; ocelli present or absent; mouth ventral, intestinal ceca occasionally fused posteriorly, occasionally with lateral diverticula; with one to several testes; sperm microtubules lying along one quarter of cell periphery, with two axonemes one of which is reduced; male copulatory organ usually sclerotized; ovary tubular, usually encircling right intestinal caecum; ventral vaginal pore sometimes present; genital pore usually median.

Habitat: Adults parasitic on skin, gills, and sometimes nasal bulbs of elasmobranchs; occasionally in coelom, oviducts, and cloaca of elasmobranchs; occasionally in cloaca of holocephalans.

Montchadskyellidea

See Figure 22 (Plate 2). Haptor with one pair of anchors lacking supporting bars, with 14 marginal hooklets; mouth subterminal, gut diverticula present; testis single; male copulatory organ sclerotized; vas deferens encircling left caecum; accessory piece present; ovary encircling right caecum; one midventral vagina present; genital pores separate, opening on separate ventral papillae.

Habitat: Adults parasitic in gut of marine teleosts.

Subclass Polyopisthocotylea**Chimaericolidea**

See Figure 23 (Plate 2). Single, weak oral sucker-like organ usually present; body with highly contractile, sometimes with very long, posterior peduncle; haptor with four pairs or four alternating rows of two short-stalked symmetrical clamps, and terminal lappet-bearing hooks; ceca with lateral diverticula, extending posteriorly into haptor; with numerous testes; seminal vesicle present or absent; cirrus muscular, armed or not; prostatic complex present or absent; ovary lobed or branched; with two lateral vaginae opening into vitelline duct; seminal receptacle present or absent; uterus with numerous longitudinal loops, with or without lateral branches.

Habitat: Adults parasitic on gills or in gill chamber of holocephalans.

Diclybothriidea

See Figure 24 (Plate 2). With anterior muscular, paired ventral “bothria” or oral sucker-like organ; haptor with three pairs of sessile suckers, with medial, haptoral appendix bearing three pairs of hook-like sclerites or one pair of terminal suckers and

two small anchors; each haptoral sucker with single, large, curved, hooked sclerite; mouth terminal or nearly so; ceca united posteriorly, with lateral diverticula; testes numerous; male intromittent organ usually armed; ovary tubular, convoluted; with two lateral vaginae; uterus preovarian; vitellarium sometimes extending posteriorly into haptor; eggs with or without polar filaments, occasionally forming chains.

Habitat: Adults parasitic on gills of sturgeon, paddlefish (chondrosteans), and elasmobranchs.

Mazocraeidea

See Figure 25 (Plate 2). With two anterior buccal suckers, occasionally enlarged in form of discoid adhesive organ with conical papillae; haptor symmetrical or asymmetrical, set off from body by distinct peduncle or not, distinctly bilobed or not, usually with four to numerous pairs of clamps, without marginal hooklets, terminal lappet usually present; terminal lappet with one to three pairs of similar or dissimilar hook-like sclerites, bifid or not; testes numerous; copulatory apparatus consisting of sheaf of long spines or longitudinally striated sheath; male intromittent organ present or absent, armed or unarmed; ovary tubular, winding, convoluted, rarely compact or inverted U-shaped; vitellarium sometimes extending posteriorly into haptor; seminal receptacle present or absent; vagina present or absent, paired or not; vaginal aperture spined or not, conical sclerite in front of vaginal pore or not; eggs with two filaments; genitointestinal canal present; genital pores common or separate, genital pore sometimes sucker-like; in rare cases (Diplozoidae) two adults permanently fused in form of an X.

Habitat: Adults parasitic on gills or occasionally mouth cavity of marine, or sometimes freshwater teleosts; sometimes on crustaceans in mouth cavity of teleosts.

Polystomatidea

See Figure 26 (Plate 2). With anterior muscular oral sucker-like organ; haptor with three but occasionally one pair of suckers, usually with one to two pairs of hamuli, sometimes with accessory spines or spurs, often with marginal hooklets, sometimes with medial appendix-like prolongation; ocelli usually absent; mouth terminal or subterminal; ceca occasionally fused posteriorly, often with lateral diverticula; testes, one to many; seminal vesicle present; male intromittent organ usually armed with hooks or spines; genitointestinal canal present; ovary compact; vitellarium rarely compact; uterus anterior or opposite ovary or reaching posterior of body; with two lateral vaginae.

Habitat: Adults parasitic in mouth, pharynx, esophagus, urinary bladder of frogs and toads and gills of tadpoles; mouth, esophagus, nasal passages, or urinary bladder of

(Bychowsky, *et al.*, 1970); 23. Chimaericolidea: adult of *Chimaericola* sp. 24. Diclybothriidea: adult of *Erpocotyle* sp. 25. Mazocraeidea: adult of *Heteraxinoides* sp. 26. Polystomatidea: adult of *Neodiplorchis* sp. Abbreviations: AN, anchor; BS, buccal sucker; CGP, common genital pore; CL, clamp; CO, copulatory organ; DE, developing embryo; FP, female genital pore; FVP, female ventral papilla; GC, genitointestinal canal; GCO, genital corona; H, hook; HA, haptoral appendix; HO, hooklet; HOR, head organ; HP, haptor; MP, male genital pore; MVP, male ventral papilla; OC, ocellus; OSL, oral sucker-like organ; PI, posterior isthmus; PRO, prostatic reservoir; S, sucker; SCL, sclerite; TB, transverse bar; TL, terminal lappet; VA, vagina.

turtles; mouth and gills of Australian lungfish; urinary bladder of urodeles; eyes of hippopotamuses.

Class Trematoda

Subclass Aspidogastrea

See Figure 27 (Plate 3). With ventral holdfast organ in form of linear series of 20–100 suckers, numerous transverse rugae, or extensive adhesive disc subdivided by septa into numerous loculi; disc with or without papillae; neodermis with microvilli in form of hemispherical microtubercles; buccal funnel at anterior end of body; oral sucker usually absent; oral lobes occasionally present; with one or two blind intestinal ceca; excretory vesicle present, V-shaped, excretory pore near posterior of body; with one, two, or many testes; sperm biflagellated, flagella incorporated into body of sperm, 9+‘1’ microtubule arrangement; cirrus present; cirrus-sac present or absent; ovary single; vitellarium follicular or tubular, if follicular usually with multiple lateral follicles, rarely single median tube flanked by follicles, if tubular, two tubes; uterus generally long; Laurer’s canal present or absent; Mehli’s gland present; eggs ectolecithal; single common genital pore.

Habitat: Adults endoparasites in kidneys, pericardial chamber, gill lamellae, or intestine of freshwater and occasionally marine lamellibranch molluscs, kidneys (renal cavities) and pericardial chamber of marine and freshwater gastropod molluscs, occasionally guts of turtles or freshwater and marine teleosts, gall bladder and bile ducts of elasmobranchs, or in lumen of rectal glands of Holocephali.

Subclass Digenea

Almost all digeneans are endoparasites as adults in various organ systems of vertebrates. They are monophyletic and are most easily characterized by their possession of a unique series of developmental stages that include miracidium, sporocyst, redia, cercaria, and metacercaria. Variation in life cycles seen among digenean species suggests that perhaps only a subset of these ontogenetic stages should be considered to distinguish the subclass. Most adult digeneans possess an anterior sucker (or oral sucker), which is usually (Figure 28, Plate 3), but not always (Figure 32, Plate 3), associated with the mouth. Most also possess a second sucker (or acetabulum) that is usually midventral (Figure 49, Plate 3), but occasionally posterior in

position (Figure 48, Plate 3). The body of some species is divided into two parts (Figure 35, Plate 3). Other major variations in adult body form include a posterior telescoping ecsoma (Figure 41, Plate 3), a sucker-like ventral adhesive tribocytic organ (Figure 35, Plate 3), one or more anterior collars of large spines (Figure 36, Plate 3), and paired anterior retractile proboscides. Most species possess an anterior mouth that opens into a bulbous pharynx and an intestine consisting of two or occasionally one blind cecum, with or without diverticula. However, the ceca in some species are connected to one another posteriorly (Figure 34, Plate 3) or open into the excretory bladder. The excretory system generally consists of two sets of protonephridia, both of which empty into a common excretory vesicle. This vesicle is variable in shape among taxa and usually opens at the posterior end of the body. With the exception of the schistosomes (Figure 51, Plate 3) and some didymozoids, all digeneans are hermaphroditic. The male intromittent organ is usually a cirrus, which may or may not be armed with spines, and may or may not be surrounded by a cirrus-sac. Testes are usually oval, but occasionally lobed or tubular; testes can be single, paired, or numerous. Sperm may be stored inside or outside the cirrus-sac in an internal or external seminal vesicle respectively; some taxa possess both vesicles. Most digeneans possess a single ovary that may be round, lobed, or tubular in form. Digeneans lack a vagina; instead, sperm enters the female system through the uterus, which opens, generally in combination with the male system, into a common genital pore. Some species possess a seminal receptacle in the form of a basal expansion of the uterus or as diverticula of the Laurer’s canal. A Laurer’s canal, which may or may not open to the outside, may be present or absent. The function of the Laurer’s canal is unknown, but it is considered by some to represent the remnant of a vagina. The vitellarium consists of columns of numerous follicles along both sides of the body in most taxa, but is occasionally present as one or a pair of compact follicles or vitelline chords.

With at least 1592 nominal genera, the digeneans are by far the most diverse of the platyhelminth groups. Unlike all of the other major platyhelminth groups, superfamily, rather than order, is the highest taxonomic category of relative stability within the subclass. Unfortunately, although the phylogenetic relationships among some of the major digenean taxa have been explored (e.g., Cribb *et al.*, 2001; Olson *et al.*, 2003), the

Plate 3 Trematoda (Figures 27–52) 27. Aspidogastrea: adult of *Aspidogaster* sp.; 28. Allocreadioidea: adult of *Crepidostomum* sp.; 29. Azygioidea: adult of *Otodistomum veliporum* 30. Transversotrematoidea: adult of *Transversotrema* sp. Abbreviations: A, adhesive disc; AC, acetabulum; AP, adhesive papillae; BF, buccal funnel; CGP, common genital pore; CS, cirrus-sac; CYC, cyclocoel; EC, ecsoma; ES, esophagus; ESV, external seminal vesicle; EV, excretory vesicle; EXP, excretory pore; FB, forebody; GY, gynecophoral canal; HB, hindbody; I, intestine; IS, internal seminal vesicle; LD, lateral diverticula of oral sucker; M, mouth; O, ovary; OS, oral sucker; PAP, papilla; PH, pharynx; SH, spiny head collar; SR, seminal receptacle; T, testis; TO, tribocytic organ; TOR, terminal organ; TP, transverse plications; TU, tubercles; U, uterus; V, vitellarium.

relationships among the 25 superfamilies and 148 families remain controversial and poorly understood. The digeneans are treated here following the classification scheme embraced in the recent CABI keys (see Gibson *et al.*, 2002; Jones *et al.*, 2005; Bray *et al.*, 2008); superfamilies are considered below in alphabetical order. It is important to note, however, that the monophyly of many of these superfamilies also remains uncertain.

To make the following diagnoses more concise, unless mentioned, it should be assumed that a superfamily possesses the following features: no specialized body regions or structures, both suckers (oral sucker and acetabulum) are present, the mouth opens into the oral sucker, a muscular pharynx is present, the gut consists of two blind intestinal ceca, they are hermaphroditic, the testes are compact and paired, the sperm are biflagellated and the flagella are incorporated into the body of the sperm, the flagella of the sperm possess a 9 + '1' arrangement of microtubules, a cirrus and cirrus-sac are present, the ovary is single, the vitellarium is follicular and the follicles are arranged in two lateral fields, there is a common genital pore, the eggs are ectolecithal and the epidermal cells of the miracidium are covered with cilia.

Allocreadioidea

See Figure 28 (Plate 3). Oral sucker with or without one or three pairs of muscular papillae; body surfaces usually unspined; genital pore opens near acetabulum; excretory vesicle I-shaped. Developmental stages: Cotyllocercous xiphidiorcercaria, ophthalmoxiphidiorcercaria, trichocercous, or homalometrine cercaria; metacercaria usually encysts in invertebrate hosts, rarely on substrate.

Habitat: Adults parasitic in digestive tract and occasionally gall bladder of marine and freshwater teleosts, or occasionally gall bladder of freshwater turtles, or intestine of chameleons; some species progenetic in insects.

Azygioidea

See Figure 29 (Plate 3). Body surface usually unspined; genital pore opens anterior to acetabulum; sinus organ present; uterus usually entirely preovarian; excretory vesicle Y-shaped. Developmental stages: Cercaria nonoculate furcocercous, furcocystocercous, or cystocercous; metacercaria unknown.

Habitat: Adults parasitic in stomach or body cavity of elasmobranchs (sharks and rays) and in stomach of freshwater teleosts and holosteans (gar, bowfin, etc.).

Bivesiculoidea

See Figure 30 (Plate 3). Oral sucker and acetabulum absent; body surface with minute spines; testis single; genital pore midventral; uterine seminal receptacle present; excretory vesicle V-shaped. Developmental stages: Cercaria furcocercous, cystophorous, oculate furcocystocercous.

Habitat: Adults parasitic in intestine of marine and occasionally freshwater teleosts.

Brachylaimoidea

See Figure 31 (Plate 3). Body surfaces spined or not; ovary usually between testes; ovary and testes often close to posterior extremity of body; genital pore opens in hindbody, often near posterior extremity; excretory vesicle Y-shaped. Developmental stages: Cercaria furcocercous or cercariaeum

with rudimentary or no tail that may or may not leave the sporocyst; metacercaria encysted or unencysted in second intermediate host or within sporocyst in second intermediate host.

Habitat: Adults parasitic in intestine of aquatic birds and terrestrial mammals, birds and occasionally reptiles and amphibians.

Bucephaloidea

See Figure 32 (Plate 3). Body surface usually spined; oral sucker and acetabulum absent; anterior holdfast organ a rhynchus, with or without sucker; mouth opening on ventral surface; intestinal caecum simple, not bifurcating; genital pore usually terminal; excretory vesicle I-shaped. Developmental stages: Cercaria of bucephalid type; metacercaria encyst in teleosts.

Habitat: Adults parasitic in digestive system or sometimes in swim bladder or body cavity of marine and freshwater teleosts and occasionally intestine of salamanders.

Clinostomoidea

See Figure 33 (Plate 3). Oral sucker weak, enveloped in collar-like anterior end of body, pharynx rudimentary or small; genital pore opens in posterior third of body. Developmental stages: Brevifurcate cercaria; metacercaria encysts on vertebrate hosts.

Habitat: Adults parasitic in mouth and esophagus of alligators and piscivorous birds.

Cyclocoeloidea

See Figure 34 (Plate 3). Oral sucker usually absent, occasionally present; acetabulum absent or, if present, weakly developed; intestinal ceca usually fused posteriorly to form cyclocoel; genital pore opens near pharynx. Developmental stages: Cercaria usually tailless or with rudimentary tail; metacercaria encysts within sporocyst or redia in molluscan host.

Habitat: Adults parasitic in nasal sinuses, nasolacrimal sinus, infraorbital sinuses, respiratory tract, and occasionally coelom or intestine of birds.

Diplostomoidea

See Figure 35 (Plate 3). Body generally divided into anterior forebody and posterior hindbody; tribocytic organ present posterior to acetabulum; reproductive organs generally concentrated in hindbody; genital pore usually opens in posterior of body. Developmental stages: Cercaria variable; metacercaria generally encysts on vertebrate hosts, very rarely invertebrate hosts.

Habitat: Adults parasitic in digestive system of birds and reptiles, especially crocodilians and snakes, sometimes amphibians, sometimes mammals including dogs, cats, dolphins, and some monotremes.

Echinostomatoidea

See Figure 36 (Plate 3). Spiny head collar often present; two anterior, retractile, spiny proboscides rarely present; body usually spined; ceca sometimes with lateral diverticula; hermaphroditic-sac sometimes present, often with cirrus-sac, cirrus occasionally absent; genital pore variable in position. Developmental stages: Cercaria echinostome-like,

megalurous, gymnocephalous megaperid or haplospianchnid; metacercaria usually encysts on aquatic vegetation, sometimes on vertebrates, rarely in invertebrates.

Habitat: Adults parasitic in the intestinal tract, gall bladder, bile duct, liver, lungs, nasal cavity, conjunctival sac, bursa fabricius, and orbit of vertebrates including a variety of marine and freshwater teleosts, birds, crocodiles, turtles, snakes, lizards, marine mammals including pinnipeds and cetaceans, and a variety of terrestrial herbivorous mammals.

Gorgoderioidea

See Figure 37 (Plate 3). Body surfaces spined or not; acetabulum well developed, sessile or protuberant; intestinal caeca usually two, occasionally one, may unite posteriorly; cirrus-sac present or absent; genital pore usually anterior to acetabulum; vitellarium follicular or dendritic, usually limited in extent; uterus usually in hindbody; excretory vesicle variable. Larvae: Microcercous xiphidiocercaria; metacercaria encysts on invertebrates or vertebrates.

Habitat: Adults parasitic in intestine, gall bladder, bile ducts, pancreatic ducts, body and pericardial cavities, urinary bladder, ureters, swim bladder, nasal and paranasal sinuses, lungs, brain, or encysted in skin and in wall of digestive tract of a diversity of vertebrates (elasmobranchs, teleosts, herpetiles, birds, and mammals).

Gymnophalloidea

See Figure 38 (Plate 3). Mouth opening into oral sucker or acetabulum (bucephalids); cirrus-sac present or absent; cirrus sometimes absent; genital pore variable in position. Developmental stages: Cercaria often produced in branched sporocysts; cercaria often with rudimentary tail or tailless, often gasterostomous; metacercaria encysts on vertebrate hosts or within sporocyst in molluscan host; very rarely encysts in invertebrates.

Habitat: Adults parasitic in liver, bile duct, gall bladder, digestive tract of freshwater and marine teleosts, or large intestine, cloaca, bursa fabricius of birds, occasionally mammals (such as, for example, hedgehogs, rabbits, ruminants).

Haploporoidea

See Figure 39 (Plate 3). Body surfaces usually spined; eye-spot pigment usually present, dispersed in forebody; oral sucker with or without lobes or hood; testes usually one, occasionally two; cirrus-sac absent; genital pore anterior to acetabulum; excretory vesicle I-, Y-, or V-shaped.

Habitat: Adults parasitic in digestive system of marine, freshwater, and estuarine teleosts.

Haplospianchoidea

See Figure 40 (Plate 3). Body surfaces unspined; oral sucker normal, occasionally replaced by disc with or without lobes; intestinal caecum single; testis usually one, rarely two; cirrus-sac usually absent, rarely present; genital pore anterior to acetabulum; excretory vesicle Y-shaped.

Habitat: Adults parasitic in digestive system of marine, freshwater, and estuarine teleosts.

Hemiuroidea

See Figure 41 (Plate 3). Body generally elongate; sometimes with posterior telescoping ecsoma; body surface unspined but often with transverse plications; ceca sometimes fused to one another posteriorly, or fused posteriorly with excretory vesicle; usually hermaphroditic but one group (didymozoids) occasionally gonochoristic (if gonochoristic adult sexually dimorphic, male and female usually encysted in pairs); hermaphroditic duct almost always present; cirrus-sac often absent; vitellarium often in form of rosette or tubular, or in two compact masses. Developmental stages: Miracidium spinous, lacking cilia; cercaria cystophorous; metacercaria usually unencysted in invertebrate or vertebrate hosts, occasionally within redia in molluscan host.

Habitat: Adults parasitic in digestive tract or swim bladder of freshwater and marine teleosts and rarely elasmobranchs; some associated with branchial cavities of marine teleosts and elasmobranchs; occasionally in mouth of frogs or stomach of sea snakes.

Heronimoidea

See Figure 42 (Plate 3). Body surfaces unspined; oral sucker often poorly developed; acetabulum absent; genital pore at level of pharynx; testes elongate, tubular, extend for length of body; vitellarium in form of slender elongate bands, extend for much of length of body; excretory vesicle tubular. Developmental stages: cercaria amphistomate; metacercaria apparently lacking, infection of definitive host is through ingestion of cercaria in the molluscan host.

Habitat: Adults parasitic in lungs and trachea of freshwater turtles.

Lepocreadioidea

See Figure 43 (Plate 3). Body surfaces spined or not; with or without circumoral spines; oral sucker occasionally with papilliform extensions; acetabulum ventral or rarely at posterior end of body; ceca open into excretory vesicle or not; one or usually two intestinal ceca present; with two to many testes; cirrus-sac usually present, sometimes absent; hermaphroditic duct in some; external seminal vesicle in some; internal seminal vesicle bipartite in some. Developmental stages: Gymnophalous cercaria, produced in redia; metacercaria encysts on invertebrates, or on substrate, rarely in sporocyst or redia in molluscan host.

Habitat: Adults parasitic almost exclusively in digestive tract, rarely gall bladder or urinary bladder of marine teleosts; one record from lungs of reptile.

Microphalloidea

See Figure 44 (Plate 3). Body surfaces spined or not; oral sucker may be surrounded by semicircular collar of spines; acetabulum poorly developed, rarely absent; gut usually present, occasionally lacking or poorly developed (with short ceca); cirrus-sac present or absent; genital atrium sometimes with complicated accessory organs; vitellarium usually in restricted symmetrical clusters of large follicles; excretory system V-, Y-, or I-shaped. Developmental stages: Xiphidiocercaria of ubiquita, microphallous, or virgulate type; metacercaria encysts on invertebrates or vertebrates, or occasionally in sporocyst in the molluscan host.

Habitat: Adults parasitic in many organ systems of most vertebrate classes.

Microscaphidioidea

See Figure 45 (Plate 3). Body surfaces spined or not; oral sucker and acetabulum absent; part of all of ventral surface may function as accessory attachment organ; some with ventral papillae; pharynx with or without paired intra or extramural sacs; cirrus-sac absent; uterine seminal receptacle often present; excretory system entirely or partly reticular. Developmental stages: cercaria apharyngeal monostomous; metacercaria encysting on vegetation.

Habitat: Adults parasitic in digestive system of marine and freshwater teleosts, and turtles.

Monorchioidea

See Figure 46 (Plate 3). Body surfaces usually spined; oral sucker rarely with ring of spines; testes one, two, or rarely 8; uterus usually with numerous coils; terminal organ associated with terminal part of uterus in some; excretory vesicle I-, V-, or Y-shaped. Developmental stages: cercaria often microcercous or completely lacking tail, some with stylet; metacercaria often progenetic (i.e., producing eggs), encysting in molluscs, planarians, aquatic annelids and larval insects.

Habitat: Adults parasitic in digestive system of marine and freshwater teleosts.

Opisthorchioidea

See Figure 47 (Plate 3). Body sometimes spined; oral sucker sometimes with ring of spines; cirrus-sac usually lacking; hermaphroditic duct sometimes present opening into genital atrium; acetabulum sometimes enclosed in ventrogenital sac, with or without gonotyl; seminal vesicle when present often bipartite. Developmental stages: Cercaria generally with ocelli, pleurolophocercous, parapleurolophocercous or gymnocephalus cercaria; metacercaria encysts on vertebrates, rarely invertebrates.

Habitat: Adults parasitic in stomach, intestine, occasionally bile ducts of marine teleost fishes, snakes, lizards, birds, and mammals; occasionally ovary of freshwater teleosts; occasionally progenetic encysted in musculature of frogs.

Paramphistomoidea

See Figure 48 (Plate 3). Usually unspined; oral sucker often with paired lateral diverticula, occasionally one unpaired diverticulum; acetabulum posterior or subterminal, sometimes with muscular lip, occasionally lacking; body occasionally with caudal appendages; usually with lymphatic system (usually with one to three longitudinal trunks); genital sucker sometimes present; ventral pouch sometimes present; cirrus-sac present or absent; hermaphroditic-sac in some. Developmental stages: Cercaria lacking acetabulum or with posterior acetabulum, develops from redia or branched sporocyst; metacercaria usually encysts on vegetation, but occasionally on frogs, metacercarial stage occasionally lacking.

Habitat: Adults parasitic in digestive tract of marine and freshwater teleost fishes, snakes, marine turtles, amphibians, birds and a wide diversity of marine and terrestrial mammals (including humans), or in lungs and trachea of turtles and tortoises.

Plagiorchioidea

See Figure 49 (Plate 3). Body usually spined; oral sucker occasionally with pair of muscular lateral papillae; acetabulum rarely vestigial; fields of vitellarium usually restricted anteriorly and posteriorly; excretory vesicle Y-shaped. Developmental stages: Cercaria of leptocercous, microcercous, cystocercus, armatao, ornatae, virgulate, ubiquita, or coracriaeum type; often developing in daughter sporocysts in gastropod or lamellibranch molluscs; metacercaria encysts in terrestrial arthropods or gastropods.

Habitat: Adults parasitic in digestive system of mammals (especially bats), turtles, amphibians, reptiles, and occasionally fishes; liver and bile ducts of mammals, birds, and reptiles; cloaca and oviducts of birds and mammals; bursa fabricius of birds; urinary bladder of fishes and amphibians; coelom or pericardial chamber of elasmobranchs; occasionally progenetic in leeches and crustaceans.

Pronocephaloidea

See Figure 50 (Plate 3). Body surfaces spined or unspined; acetabulum absent; often with ventral longitudinal ridge or series of ventral papillae; head collar present or absent; pharynx absent; male and female pores occasionally separate, pore(s) variable in position; uterus usually in form of transverse coils anterior to ovary; vitellarium follicular, rarely in form of single lobed mass; excretory vesicle V- or Y-shaped, sometimes extremely modified in structure; posterior invaginations of body forming secondary excretory vesicle or protrusible tentacles associated with excretory vesicle. Developmental stages: Cercaria monostomate, bi or trioculate, with posterior adhesive glands at posterior of body; metacercaria encysts on substrate or on invertebrate hosts, rarely in sporocyst or redia within molluscan host.

Habitat: Adults parasitic in oviduct, urinary and gall-bladders, pancreas, liver, respiratory tract, tissues or digestive system of teleosts, marine turtles, marine iguanids, birds, mammals (including dugongs, cetaceans, bats, rodents, and insectivores), occasionally in bursa fabricius of birds.

Schistosomatoidea

See Figure 51 (Plate 3). Gonochoristic or hermaphroditic, if gonochoristic, male with ventral gynecophoral canal in which female resides for much of her life; surface of male body often with tubercles, with or without spines; pharynx usually lacking; both oral sucker and acetabulum present, or one or both lacking; ceca of gut often anastomosing at several points along length; one, two or many testes; genital pores separate or combined. Developmental stages: Cercaria apharyngeate, brevifurcate, sometimes also lophophorate; metacercarial stage lacking; cercaria develops into schistosomula; first host usually a mollusc but rarely an annelid.

Habitat: Adults parasitic in blood vessels or heart of freshwater and marine teleosts, elasmobranchs, holocephalans, usually freshwater (but sometimes marine) birds and mammals (including humans), crocodiles, and marine and freshwater turtles.

Transversotrematoidea

See Figure 52 (Plate 3). Body transversely elongated; spined; ceca united posteriorly to form transverse cyclocoel; excretory

vesicle curved to right, receiving collecting vessels from both sides of body; cirrus absent; genital pore anterior. Developmental stages: Cercaria brevifurcate with pair of anterior lateral appendages; metacercarial stage lacking; cercaria infects definitive host cutaneously and develops directly into adult stage.

Habitat: Adults parasitic under scales of freshwater, brackish water, and marine teleosts.

Class Cestoda

The cestodes, or tapeworms, conspicuously differ from almost all other platyhelminth groups in their lack of all elements of a digestive system, the only exceptions perhaps being the amphilinideans and gyrocotylideans, the anterior attachment organ of which is considered by some to represent a vestige of a digestive system. Thus, in general, the cestodes have no mouth, pharynx, esophagus, or intestine at any stage in their development. Rather, they absorb nutrients, in the form of very small molecules, directly through the outer layer of their body. There is evidence to suggest that their unique neodermal surface extensions, known as microtriches, assist in this process. Microtriches typically consist of an outer electron-dense cap composed of cap tubules, a baseplate, and a basal core consisting of an extension of the cytoplasm of the tegument (Figure 16). The entire structure is surrounded by a plasma membrane. These structures may also assist with attachment. Microtriches appear to be of two basic types. The larger form, termed a spinithrix (pl. spinitriches) (SPT in Figure 16), is greater than 200 nm in width; the smaller form, termed a filithrix (pl. filitriches) (FIT in Figure 16), is less than or equal to 200 nm in width.

The majority of tapeworms have a body consisting of an attachment region called the scolex, followed by a series of compartments, termed proglottids, that are collectively referred to as the strobila. Scolex morphology varies significantly among the various tapeworm orders. The scolex is simple in some groups, but it is more commonly equipped with attachment structures such as hooks, suckers, loculi, or hooked tentacles. In some groups, the scolex is subdivided into two or four flexible bothria or four muscular bothridia. Bothridia can be distinguished from bothria in their possession of discrete inner and outer membranes bounding their musculature, visible most readily in histological section.

The proglottids of most tapeworms are hermaphroditic, each containing one, or less commonly two or more, sets of male and female reproductive organs. A few orders of tapeworms (specifically the amphilinideans, gyrocotylideans, and caryophyllideans) lack proglottids and also possess only a single set of male and female reproductive organs rather than multiple sets (i.e., they are monozoic rather than polyzoic). The members of one order of tapeworms, the spathebothriideans, lack distinct proglottids but possess multiple sets of reproductive organs arranged in a linear series (i.e., they are nonproglottized but polyzoic). The majority of tapeworms, however, are proglottized, and each proglottid bears one or more sets of reproductive organs (i.e., they are proglottized and polyzoic). In proglottized tapeworms, a germinative region located directly behind the scolex consecutively produces

the proglottids of the strobila. Thus, the proglottid nearest the scolex is the youngest, and that furthest from the scolex is the oldest. In some tapeworms, the posterior-most proglottids, on reaching a certain level of maturity, drop from the strobila (apolytic) and may continue development independent of the main body of the worm. In other tapeworms, the proglottids are retained on the strobila essentially throughout the life of the animal (anapolytic). In the former instance the proglottids may complete the production of eggs independent of the strobila; in the latter case proglottids on the strobila produce eggs that are released through uterine pores or tears. Degrees of apolysis are often recognized. Thus, cestodes that drop mature proglottids are considered to be euapolytic; those that drop immature proglottids are considered to be hyperapolytic. Proglottids filled with eggs are termed gravid. Consecutive proglottids either overlap (craspedote) or not (acraspedote). A very few species exhibit proglottids that, rather than being hermaphroditic, are either male or female. Because these proglottids are found on the same strobila, individuals of these species are considered to be hermaphroditic, but the proglottids themselves are not. There is, however, evidence of gonochorism (separate sexes) in individuals of a few tapeworm species in which all of the proglottids of the strobila are either entirely male or entirely female.

With at least 751 recognized genera, the cestodes are the second most diverse group of platyhelminths. The most recent comprehensive systematic treatment of the group is that of Khalil *et al.* (1994), in which 14 orders were recognized. However, since then, the class has been revised to consist of 18 orders. The bothriate tapeworm orders are considered to be earlier divergent lineages than the acetabulate tapeworm orders (i.e., those with suckers or bothridia), but the relationships among the acetabulate orders remain controversial, as does membership in some of the elasmobranch-parasitizing orders.

The terms Cestoidea, Cestodaria, and Eucestoda are also sometimes used in reference to tapeworms. The term Cestoidea is synonymous with the term Cestoda; the authors have followed Hyman (1951) and Grassé (1961) in using the term Cestoda here. In the past, the amphilinideans and gyrocotylideans have been collectively referred to as the Cestodaria. However, evidence against the monophyly of this group is mounting, and, thus, the Cestodaria is not recognized here. The term Eucestoda is used to collectively refer to the cestodes other than the amphilinideans and gyrocotylideans. The monophyly of the Eucestoda is fairly well accepted; members of this subclass can be distinguished from the amphilinideans and gyrocotylideans, for example, in their possession of a scolex and also in that their sperm lack mitochondria.

To make the following diagnoses more concise, unless otherwise indicated, it should be assumed that an order possesses an anterior scolex of some form, lacks all vestiges of a digestive system, and possesses a strobila consisting of numerous proglottids that each contain one full set of both male and female reproductive organs (polyzoic). These proglottids contain numerous, compact testes filling much of the region anterior to the ovary, sperm lacking a mitochondrion, flagella that are incorporated into the main body of sperm, 9 + '1' microtubule arrangement in the flagella of the sperm, a cirrus

armed with microtriches, a cirrus-sac, a single posterior ovary, a vitellarium consisting of numerous follicles that extend in two lateral bands, one down each side of the proglottid, a Mehlis' gland located posterior to the ovarian bridge, a uterus that is sacciform, and male and female systems that open through a combined lateral genital pore, with pores of consecutive proglottids alternating irregularly down the length of the strobila.

Amphilinidea

See Figure 53 (Plate 4). Distinct scolex absent but with anterior coniform "sucker;" one set of male and female reproductive organs (monozoic) present; testes in two lateral bands; sperm with mitochondrion; cirrus-sac absent, ovary varying in shape; preformed uterine pore anterior; uterus often N-shaped or sinuous; seminal receptacle present; genital pores usually separate, posterior.

Habitat: Adults parasitic in body cavity of chondrosteans, some freshwater and marine teleosts, and Australian freshwater turtles.

Gyrocotylidea

See Figure 54 (Plate 4). Distinct scolex absent but with anterior "sucker;" rosette usually present at posterior end of body; body usually "spined" (spines are likely to be microtriches), "spines" limited in distribution or not; excretory system reticulate; one set of male and female reproductive organs (monozoic) present; sperm with mitochondrion; cirrus-sac absent; ovary follicular, in V- or U-shaped band around seminal receptacle; seminal receptacle present; uterus sinuous, in median region of anterior part of body, terminal portion expanded into sac, opening into preformed ventral uterine pore; genital pores separate, both anterior.

Habitat: Adults parasitic in spiral intestine of holoccephalans.

Subclass Eucestoda

Bothriocephalidea

See Figure 55 (Plate 4). Small to large tapeworms; scolex with two lateral bothria, occasionally with posterior appendages, occasionally divided into two or several vertical loculi, with or without muscular apical disc, occasionally replaced by scolex deformatus or pseudoscolex; each bothrium usually unarmed, occasionally armed with one pair of hooks or apical series of hooks; proglottization usually complete; proglottids usually craspedote, usually wider than long; anapolytic, usually with

one set of male and female reproductive organs per proglottid, rarely with two sets per proglottid; cirrus unarmed or armed; combined genital pore dorsal, median, sublateral or lateral, irregularly alternating; ovary posterior, medullary, mostly bilobed; vitelline follicles usually cortical, medullary or both, in two extensive lateral bands or circumsegmental; uterus variable, consisting of winding uterine duct and compact or diverticulate uterine sac; preformed uterine pore present or absent, if present opening posterior to genital pore.

Habitat: Adults parasitic in intestine of teleosts, rarely salamanders.

Caryophyllidea

See Figure 56 (Plate 4). Scolex usually with one to three pairs of weakly developed shallow depressions or grooves (considered to be loculi if temporary, bothria if more permanent), occasionally with terminal introvert or disc; with one set of male and female reproductive organs (monozoic); ovary H- or dumbbell-shaped; vitellarium usually preovarian, occasionally postovarian follicles also present; seminal receptacle present or absent; uterus often sinuous; female pore a combined utero-vaginal pore; genital pores separate or combined, median, ventral.

Habitat: Adults parasitic in intestine of siluriform and cypriniform freshwater fishes.

Cathetocephalidea

See Figure 57 (Plate 4). Large worms; scolex in form of single transversely expanded fleshy organ, lacking all signs of acetabula, bothria, and armature; usually with one strobila per scolex, rarely with multiple strobilae per scolex; proglottids acraspedote, euapolytic; with one set of male and female reproductive organs per proglottid; testes in single field; ovary H-shaped in dorso-ventral view; vitelline follicles circumsegmental; preformed uterine pore absent; vagina extending anterior to cirrus-sac; combined genital pore lateral; genital pores alternating irregularly along length strobila.

Habitat: Adults parasitic in spiral intestine of whaler sharks.

Cyclophyllidea

See Figure 58 (Plate 4). Scolex usually with four round suckers; suckers armed with spines or not; often with apical organ in form of single sucker (rarely four apical suckers), some with apical, often protrusible rostellum; rostellum armed with one or two rings of hooks or not, with or without rostellar pouch; scolex divided into scolex and metascolex, or with pseudoscolex in some; proglottids craspedote or acraspedote;

Plate 4 Cestoda (Figures 53–70) 53. Amphilinidea: adult of *Amphilinia* sp. (Gibson in Khalil, *et al.*, 1994); 54. Gyrocotylidea: adult of *Gyrocotyle* sp. (Gibson in Khalil, *et al.*, 1994); 55. Bothriocephalidea: adult of *Bathystecus brayi*. (Kuchta and Scholz, 2004); 56. Caryophyllidea: adult of *Paraglaridacris* sp. (Mackiewicz in Khalil, *et al.*, 1994); 57. Cathetocephalidea: adult of *Sanguilevator yearsleyi*; 58. Cyclophyllidea: adult of *Echinococcus* sp.; 59. Diphyllidea: adult of *Echinobothrium* sp.; 60. Diphyllbothriidea: adult of *Diphyllbothrium* sp.; 61. Haplobothriidea: adult of *Haplobothrium* sp.; 62. Lecanicephalidea: adult of *Corrugatocephalum* sp.; 63. Litobothriidea: adult of *Litobothrium daileyi*; 64. Nippotaeniidea: adult of *Nippotaenia* sp. (Bray in Khalil, *et al.*, 1994); 65. Proteocephalidea: adult of *Proteocephalus* sp.; 66. Rhinebothriidea: adult of *Rhinebothrium megacanthophallus*; 67. Spathebothriidea: adult of *Spathebothrium* sp.; 68. Tetrabothriidea: adult of *Tetrabothrius* sp.; 69. "Tetraphyllidea": adult of *Acanthobothrium* sp.; 70. Trypanorhyncha: adult of *Pterobothrium* sp. Abbreviations: APO, apical organ; AS, apical sucker; BO, bothrium; BOD, bothridium; CGP, common genital pore; CPE, cephalic peduncle; CPS, cruciform pseudosegments; FP, female genital pore; GP, gravid proglottid; H, hook; IMP, immature proglottid; L, loculus; MA, muscular appendage; MB, muscular bulb; MP, male genital pore; MPR, mature proglottid; MUP, muscular pad; PA, pars apicalis; PB, pars basalis; PRG, proglottid; PSC, primary scolex; PST, primary strobila; R, rosette; RO, rostellum; S, sucker; SCO, scolex; SK, stalk; SSC, secondary scolex; SST, secondary strobila; STR, strobila; TE, tentacle; TS, tentacle sheath; U, uterus; UP, uterine pore.

apolytic or anapolytic; usually with one but rarely two strobilae per scolex; usually with one but occasionally two sets of male and female reproductive organs per proglottid; strobila rarely with proglottids that are entirely either male or female, or male and female proglottids that alternate regularly along strobila; testes, one to many, usually anterior to ovary, occasionally posterior to ovary; cirrus-sac usually present; cirrus usually armed with spiniform microtriches, occasionally with stylet, occasionally with accessory sac; external and internal seminal vesicles present or absent; ovary dumbbell-shaped, or asymmetrical; vitellarium usually single compact mass, occasionally bilobed mass, usually posterior to ovary; vagina present or absent, replaced functionally by cirrus-sac and modified male duct, or replaced by supplementary ducts running between seminal receptacles in consecutive proglottids in some taxa; uterus ring-shaped, or saccate, with or without lateral branches (diverticula), or reticular, transverse in some, replaced by parauterine organ(s) in some, replaced by uterine capsules or parenchymatous egg capsules in some, uterus single or double, usually with preformed uterine pore; common genital pore lateral, rarely midventral; genital pores occasionally regularly alternating or unilateral along strobila; genital atrium conspicuous or not, with or without prominent radial musculature; vagina usually posterior to cirrus-sac, occasionally dorsal to ventral to cirrus-sac.

Habitat: Adults parasitic in intestine of amphibians, snakes, lizards, birds, or mammals.

Diphyllidea

See Figure 59 (Plate 4). Scolex with two bothria, proximal surfaces of bothria occasionally with spines; scolex with apical organ; apical organ usually armed with one row of large hooks on dorsal and ventral surfaces, often with continuous or interrupted row of smaller hooklets on lateral margins, occasionally with small spines; bothria supported by cephalic peduncle; cephalic peduncle often armed with eight columns of straight hooks with trifid bases; proglottids acraspedote; generally apolytic; testes usually filling proglottid anterior to ovary; ovary H-shaped in dorso-ventral view; lateral bands of follicles of vitellarium occasionally extending medially; preformed uterine pore absent; vagina posterior to cirrus-sac; common genital pore median, ventral.

Habitat: Adults parasitic in spiral intestine of rays, skates, and sharks of families Hemiscyllidae, Scyliorhinidae, and Triakidae (most marine).

Diphyllbothriidea

See Figure 60 (Plate 4). Medium to large tapeworms; scolex with two bothria (one dorsal and one ventral), occasionally with posterior appendages, occasionally divided into two or several vertical loculi, with or without muscular apical disc, unarmed; proglottidization usually complete; proglottids craspedote or acraspedote, usually wider than long; anapolytic, usually with one set of male and female reproductive organs per proglottid, but occasionally multiple sets per proglottid; cirrus-sac usually thin-walled; cirrus unarmed; genital pore ventral, median, or submedian; ovary, posterior, medullary, mostly bilobed; vitelline follicles usually cortical and circumsegmental; uterus in form of spiral tube; preformed uterine pore opening posterior to genital pore.

Habitat: Adults parasitic in intestine of tetrapods, mostly mammals.

Haplobothriidea

See Figure 61 (Plate 4). Body bearing primary and secondary scoleces and strobila; primary scolex with four tentacles with spiniform microtriches at bases, each tentacle with muscular sac into which it can be withdrawn, bothria, bothridia and suckers absent; primarily strobila proglottized, but primary proglottids never develop reproductive organs on primary strobila; proglottized regions of primary strobila separate from remainder of primary strobila and develop into secondary strobilae that produce proglottids, each proglottid bearing one set of reproductive organs; anterior-most proglottid of each secondary strobila modified as secondary scolex; secondary scolex with four shallow anterior indentations surrounding central, apical dome; cirrus-sac median, anterior, cirrus armed with microtriches; testes numerous, arranged in two lateral fields; ovary inverted U-shaped; follicles of vitellarium arranged in two lateral fields, confluent in midline at anterior and posterior regions of proglottid; uterus with dilated uterine sac; preformed uterine pore present or absent; vagina posterior to cirrus-sac; seminal receptacle present; genital pores separate, median, anterior; eggs operculate.

Habitat: Adults parasitic in intestine of the bowfin, *Amia calva*.

Lecanicephalidea

See Figure 62 (Plate 4). Scolex usually divided into two parts: if present an anterior region (pars apicalis) variable in form, elongate (myzorhynchus), pad-like (metaporhynchus), sucker-like, or consisting of a crown of nonhooked tentacles; posterior region (pars basalis) usually cushion-like, often bearing four circular suckers or bothridia; proglottids, craspedote or acraspedote, usually apolytic; testes, three to many, arranged in a single or multiple columns; external seminal vesicle usually present, often conspicuous, extending to near posterior margin of proglottid; ovary bilobed, multilobed or irregular in dorso-ventral view; follicles of vitellarium sometimes encircling proglottid; preformed uterine pore absent; vagina present or absent, almost always posterior to cirrus-sac; cirrus armed or not; combined genital pore lateral; genital pores alternating irregularly along length strobila.

Habitat: Adults parasitic in spiral intestine of marine elasmobranchs, primarily rays.

Litobothriidea

See Figure 63 (Plate 4). Worms small; scolex with cup-shaped apical sucker and three to five pseudosegments, some pseudosegments cruciform, with or without posterior spine-like structures; proglottids slightly craspedote, euapolytic; testes arranged in two to multiple columns; cirrus armed; ovary inverted U-shaped in dorso-ventral view; vitelline follicles encircling proglottid; preformed uterine pore absent; vagina opening at same level as cirrus-sac; combined genital pore lateral; genital pores alternating irregularly along length strobila.

Habitat: Adults parasitic in spiral intestine of marine lamniform sharks.

Nippotaeniidea

See Figure 64 (Plate 4). Scolex in form of single apical sucker; proglottids acraspedote, anapolytic or apolytic; testes restricted to previtelline medulla of proglottid; cirrus-sac thin-walled; convoluted ejaculatory duct present; seminal vesicle present or absent; ovary dumbbell-shaped in dorso-ventral view, vitellarium consisting of two symmetrical compact masses, anterior to ovary; uterus in form of transverse coils in medulla, lacking preformed uterine pore; vagina opening posterior to cirrus-sac.

Habitat: Adults parasitic in digestive system of freshwater teleosts.

Proteocephalidea

See Figure 65 (Plate 4). Scolex usually with four round suckers or bothridia; suckers or bothridia uni-, bi-, tri-, or tetra-loculate; apex of scolex sometimes with armed rostellum, or large sucker, or occasionally with apical organ in form of two lappets; metascolex sometimes present as wrinkled region posterior to suckers that may or may not cover suckers of scolex; scolex with or without gland cells; proglottids craspedote or acraspedote, usually anapolytic; longitudinal muscle bundles usually conspicuous, occasionally inconspicuous; ovary usually dumbbell-shaped in dorso-ventral view; uterus usually with lateral branches (diverticula) when gravid, opening through one or more longitudinal apertures; vagina usually anterior to, but occasionally posterior to, cirrus-sac; genital pores rarely separate, lateral, alternating irregularly along length strobila; distinction between cortex and medulla usually marked.

Habitat: Adults parasitic in intestine of freshwater teleosts, occasionally in amphibians, terrestrial lizards (such as, e.g., *Varanus*, monitor lizards) and snakes.

Rhinebothriidea

See Figure 66 (Plate 4). Small to medium worms; scolex with four stalked, unarmed bothridia with facial septa; with or without myzorhynchus and marginal septa; proglottids craspedote or acraspedote, generally euapolytic; post-poral testes usually lacking; cirrus armed; ovary H-shaped in dorso-ventral view; vitelline follicles usually in two lateral fields, occasionally encroaching on median line; preformed uterine pore absent; vagina opening anterior to cirrus-sac; combined genital pore lateral; genital pores alternating irregularly along length strobila.

Habitat: Adults parasitic in spiral intestine of marine and freshwater batoid elasmobranchs.

Spathebothriidea

See Figure 67 (Plate 4). Scolex usually bearing one or two sucker-like attachment organs, but occasionally absent; osmoregulatory system in form of canals on each side of strobila, with irregular commissures and lateral pores; body proglottization absent; with multiple sets of male and female reproductive organs serially repeated down body (polyzoic); testes in two irregular lateral bands that extend throughout the length of the body; ovary rosette-shaped or bilobed, median, posterior to genital pores; small seminal receptacle occasionally present; uterus often sinuous, with median pore; male and female pores separate, opening close to one another along

median line, usually irregularly alternating in adjacent proglottids between opening dorsally and ventrally.

Habitat: Adults parasitic in intestine of freshwater, brackish water and marine chondrosteans and teleosts.

Tetrabothriidea

See Figure 68 (Plate 4). Scolex usually with four muscular bothridia; bothridia round, rectangular or occasionally triangular in form, often with auriculate muscular appendages; auricles sometimes fused to form apical "organ;" apical rostellum present or absent; proglottids craspedote; anapolytic; testes, few to many; ovary bilobed or highly lobed in dorso-ventral view; vitellarium in form of single compact mass, usually anterior to ovarian bridge; uterus transverse, with one or more dorsal pores; seminal receptacle present or absent; vagina occasionally armed; genital pores combined or not; genital atrium often muscular, sometimes with distinct male atrial canal, or genital papilla, occasionally armed; genital pores usually unilateral along length of strobila; vagina usually posterior to cirrus-sac.

Habitat: Adults parasitic in intestine of seabirds, pinnipeds, and cetaceans.

"Tetraphyllidea"

See Figure 69 (Plate 4). Scolex divided into four muscular sessile or pedunculated bothridia of a variety of forms; bothridia with or without apical muscular pad, with or without one or two pairs of uni, bi, or tripronged hooks, may or may not be further subdivided into loculi; muscular pad with or without one or three accessory suckers; metascolex occasionally present; proglottids craspedote or acraspedote, generally euapolytic; rarely with proglottids that are either male or female (or female proglottids retain male copulatory apparatus); ovary usually H-shaped, occasionally A-shaped in dorso-ventral view; vitelline follicles sometimes completely encircling proglottid, rarely condensed around ovary; uterine pores sometimes present, but not preformed, or uterus opening through median slits in uterine wall; vagina opening anterior to cirrus-sac; genital pores rarely separate, alternating irregularly or rarely unilateral along length of strobila. The order is almost certainly not monophyletic as currently configured.

Habitat: Adults parasitic in spiral intestine of marine and freshwater elasmobranchs or very rarely holocephalans.

Trypanorhyncha

See Figure 70 (Plate 4). Scolex with four retractable, hollow tentacles each armed with numerous spiral rows of hooks (hook patterns of enormous taxonomic importance); each tentacle everted and retracted by rhyncheal apparatus consisting of tentacle sheath, and retractor muscle originating within posterior muscular bulb (tentacles and rhyncheal apparatus rarely absent); scolex with two or four bothria and elongated peduncle housing rhyncheal apparatus; proglottids craspedote or acraspedote, apolytic or anapolytic; usually with one set of male and female reproductive organs per segment, but occasionally with two sets; cirrus-sac or hermaphroditic-sac usually present; external, internal and accessory seminal vesicles present or absent; ovary usually H-shaped in dorso-ventral view; follicles of vitellarium lateral or completely

encircling proglottid; uterus tubular or branched, with or without preformed uterine pore; vagina usually opening posterior to cirrus-sac, occasionally dorsal or ventral to cirrus-sac; common genital pore often associated with muscular lips.

Habitat: Adults parasitic in spiral intestine, stomach, rarely gall bladder, of elasmobranchs.

Nervous System

A bewildering variety of neural organization and complexity characterizes the platyhelminths (e.g., see [Halton and Gustafsson, 1996](#)). The basic plan involves an apical subepidermal brain consisting of multiple neurons, which can be uni, bi (especially in Neodermata), or multilobed. This is a true brain because it controls reflexes in the peripheral nerve net. The number of nerve cells (neurons) in the brain varies between 50 and 550 in free-living species, but this number is less well known for the neodermatans. The brain is generally connected to two, or sometimes more, main longitudinal nerve cords, each consisting of axons with cell bodies distributed at irregular intervals along the length of the cords. These main nerve cords are usually connected to one another by numerous transverse commissures in a ladder-like arrangement. In addition, a peripheral array of nerve plexuses (or nerve-nets) is found throughout the body. The attachment organs and the components of the female reproductive system involved in egg formation are especially well supplied with nerve plexuses, but plexuses are also found associated with the pharynx and intestine and below the surface and below the muscle layers of the body. There are separate plexuses for sensory, integrative and motor activities. The central nervous system (brain plus main cords) is more emphasized in neodermatan groups than in non-neodermatan groups. Cestodes may exhibit regional differences in the complexity of the subtegumental plexuses along the length of the body. Transmission electron microscopy suggests that platyhelminths exhibit an extensive diversity of types of sensory receptors.

Several different neuronal cell types are present, including unipolar, bipolar, and multipolar cells. Although unipolar neurons are generally confined to the ganglia of the brain and longitudinal nerve cords, cells of plexuses are dominated by bipolar cells. Individual neurons are highly secretory and contain a variety of types of vesicles in their cytoplasm. Platyhelminths utilize a diversity of signaling molecules and at least two different groups of neuropeptides. The nervous systems of platyhelminths appear to possess compounds similar to all of the major neurotransmitters known in taxa as complex as vertebrates. In addition, there are two groups of neuropeptides that appear to be unique to flatworms: neuropeptide F and FMRPamide-related peptides (FaRPs) both of which are fairly extensively distributed among the various platyhelminth groups. The existence of glial or glial-like cells in platyhelminths remains somewhat controversial.

Feeding and Digestion

Other than a few fecampiids, dalyelloids, and the cestodes, flatworms generally have a digestive system divisible into a

foregut and a caecum. The foregut leads from the mouth to the blind-ended sac-like caecum that is lined with a thin gastrodermis. Free-living species tend to be microphagous or predatory and feed on bacteria, unicellular alga, protists, and almost all types of invertebrates. Characteristically, the free-living species have a highly muscular suctorial pharynx. Depending on the species, the pharynx can be protruded, inserted, applied to, extended over, or used to envelop and swallow whole the various foodstuffs they actively seek or encounter. Food passes from the mouth *via* the pharynx to the esophagus and then to the caecum. The gastrodermis has glandular and phagocytic cells that digest and incorporate the nutrients. A number of free-living platyhelminths (e.g., prolecithophorans, rhabdocoels, polyclads) harbor endosymbiotic algae that serve as an additional source of food. The solid waste products of free-living species are often released *via* a genitointestinal canal, rather than a separate anus; in some groups (e.g., polyclads), anal pores assist with this function.

Symbiotic and parasitic platyhelminths vary their feeding habits according to the hosts on, or in, which they live. Groups that possess suckers may have numerous secretory cells and sensory structures surrounding the mouth and sucker. Although similar in basic design to the foregut of free-living groups, the parasitic groups tend to exhibit distinct cell type configurations in the gastrodermis. In these groups, the junction between the foregut and caecum is invariably abrupt. Aspidogastreans have a single cell type in their gastrodermis that alternates cyclically between a secretory-absorptive phase and an autophagic-exocytotic phase. Digeneans have a syncytial or cellular gastrodermis with only one cell type, and digestion takes place extracellularly in the lumen of the caecum. There is evidence, however, that some digeneans are capable of acquiring nutrients directly through microvillar extensions of their body surfaces. In contrast, digestion in the caecum of monogeneans is intracellular. The polyopisthocotylean monogeneans are blood-feeders. The non-pigmented cells in these taxa are thought to support and protect the pigmented digestive cells in the gastrodermis. In addition, at least some of these taxa possess a buccoesophageal canal between the buccal cavity and the esophagus that permits regurgitation of intestinal contents. The monopisthocotyleans feed on the epidermal cells and mucus of their host and have only a single gastrodermal cell type involved with endocytosis and digestion.

In the Cestoda and some symbiotic fecampiids all vestiges of a digestive system have been lost. These species rely solely on acquiring nutrients through their outer body wall. Among the Cestoda, and indeed all other neodermatans, the neodermis plays an active role in the biochemical transport of nutrients. In cestodes the surface area of the neodermis is markedly increased by the presence of microtriches, which enhance the availability of readily available nutrients to be actively absorbed into the parasite's body.

Excretion and Osmoregulation

The excretory system of platyhelminths is thought to function primarily in osmoregulation, with the removal of metabolic

wastes generally occurring by way of diffusion through the outer body layer. However, removal of excess water can also be achieved through the gut, and in free-living species it is not uncommon to find excretory products stored in various tissues. In platyhelminths, this system is made up of a series of protonephridia and is thus commonly referred to as a protonephridial system. It consists of a series of protonephridia connected to collecting ducts that empty into one or more major canals termed nephridioducts; these either open to the outside of the body through one or more nephridiopores or empty into a common excretory vesicle which opens to the outside through a common nephridiopore. All protonephridia consist of at least one flame bulb bearing two to many cilia, and a canal cell and sometimes also a cap cell. Rohde (1991) recognized three distinct types of protonephridia. In Type 1, found only in catenulids, each flame bulb has a cap cell, lacks a canal cell, and bears only two cilia, the rootlets of which extend along the collecting weir. In Type 2, found in most platyhelminths and also many other phyla including nemertines and gnathosomulids, each flame bulb has a cap cell and multiple cilia, the rootlets of which extend into the cap cell; each flame bulb is also associated with a canal cell that it may share with other flame bulbs. In Type 3, found only in kalyptrorhynchs, "dalyellioids," temnocephalids, and potentially also "typhlophanoids" and the "lecithoepitheliata," each flame bulb bears multiple cilia, but lacks a cap cell; each flame bulb is also associated with a canal cell that it usually shares with other flame bulbs. In all cases, the flame bulb is associated with a filtering apparatus, called a weir, which consists of processes of the cap and canal cell that are surrounded by a membrane. The beating of the cilia in the flame bulb draws body fluids across the membrane of the weir into the collecting ducts. One or two sets of protonephridia are present in all platyhelminths except a few catenulids in which excretion is thought to take place solely through the digestive syncytium. The protonephridial system is most developed in freshwater species. Indeed, this system is considered to have played a major role in allowing platyhelminths to invade freshwater habitats.

The protonephridial system of most platyhelminth taxa is paired (but the pairs are sometimes connected medially), consisting of two nephridioducts, one running along the lateral margin of each side of the body; these ducts connect to many protonephridia throughout their length. Some of the catenulids are exceptional in their possession of a single dorsal nephridioduct that opens through a single posterior nephridiopore; some proseriatans also possess a single set of protonephridia, but some possess three sets of protonephridia. In most of the non-neodermatan groups, the two nephridioducts open to the outside of the body through separate nephridiopores that are found in the anterior half of the body, generally on the ventral surface. In most temnocephalideans, the two nephridioducts open into separate, saccate excretory vesicles, located in the anterior of the body on either side of the pharynx, and the left and right sets of protonephridia are generally connected by two transverse ducts, one at the anterior and one at the posterior aspect of the system. The protonephridial system of monogeneans is similar to that of temnocephalidans, but the anterior transverse duct is absent in the polyopisthocotyleans.

The aspidogastreans possess a protonephridial system that is also much like that of the temnocephalidans but without the transverse ducts. The protonephridial system of digeneans differs somewhat from that of the aspidogastreans in that the two nephridioducts generally open into a common posterior excretory vesicle. This vesicle takes on a number of different forms in different taxa; for example, it can be V-, Y-, or I-shaped. Unlike other platyhelminth taxa, the arrangement of the protonephridia relative to the nephridioducts is regular and consistent in the cercarial stage of digeneans among individuals of the same species, but differs among individuals of different taxa, and thus this "flame cell formula" is often of significant taxonomic value. The larger number of flame bulbs and the difficulty of seeing most of the elements of the protonephridial system in the more robust bodies of the adult digeneans reduce the taxonomic utility of the flame bulb arrangement in adults.

Among tapeworms, the amphilinideans possess a protonephridial system consisting of a network of collecting ducts, rather than just two lateral nephridioducts. This network empties into an elongated excretory vesicle that opens to the outside through a posterior nephridiopore. The flame bulbs are usually found in pairs, grouped in clusters throughout the length of the body. The gyrocotylidean system also includes two longitudinal nephridioducts that are connected to one another by a number of secondary canals. The main nephridioducts open into a nephridiopore on the dorsal surface in the anterior half of the body. In most of the other cestode groups the protonephridial system consists of two dorsal and two ventral longitudinal nephridioducts, the ventral ducts generally being larger in diameter than the dorsal ducts; the nephridioducts are connected to multiple flame bulbs throughout the length of the body. Some cestodes do, however, have up to 12 longitudinal ducts. The pairs of dorsal and ventral nephridioducts are connected to one another in the scolex, where they may undergo extensive winding. The left and right nephridioducts are often connected to one another by way of transverse excretory ducts located in the posterior end of each proglottid; this condition is most commonly found in anapolytic eucestode species. In some groups, the longitudinal vessels are connected to one another with numerous lateral nephridioducts, resulting in a network-like arrangement of vessels. In the first proglottid formed (located at the posterior end of the strobila) the ventral pair of nephridioducts often empty into a small vesicle at the posterior end of this proglottid. However, once this proglottid drops from the strobila, the ventral vessels open to the outside separately in the posterior end of the terminal proglottid of the strobila. Rohde (1991) provides a useful overview of the evolution of the protonephridial system in platyhelminths.

Reproduction

Most platyhelminth species undergo sexual reproduction. Given the predominance of hermaphroditism in this phylum, there is some question about the relative frequency and importance of self- versus cross-fertilization in most species. In the few taxa in which this issue has been investigated in detail, cross- rather than self-fertilization appears to be the dominant

form of sexual reproduction. Gonochorism does, however, occur in some triclads, rarely in prolecithophorans, in a few fecampiids (e.g., *Kronborgia*), within the digenean family Schistosomatidae, and in a few tetraphyllidean and cyclophyllidean cestodes. To date, no instances of gonochorism in aspidogastreans or monogeneans are known. Most platyhelminths are simultaneous hermaphrodites, each individual possessing a full complement of male and female reproductive systems. There is a general tendency for the male system to mature before that of the female (protandry). Sperm transfer usually occurs during copulation. But, in a few species of macrostomids, catenulids, triclads, polyclads, rhabdocoels, polyopisthocotylean monogeneans, and cestodes, sperm is injected directly through the body wall and then migrates through the body to the female reproductive organs. Fertilization is always internal.

Asexual multiplication in one form or another is also found in a number of platyhelminths, either in the adult or, most commonly in neodermatans, in one or more of the larval stages. Adults of many of the catenulids and macrostomids undergo forms of asexual multiplication either as paratomy (regeneration before fission) or as architomy (regeneration after fission). These phenomena result in a linear chain of individuals that eventually separate and each develop into a mature worm.

Some adult triclads possess the ability to regenerate complete individuals from, in some cases, a very small portion of the body of the original individual. For example, it is possible to divide an adult freshwater triclad posterior to the pharynx and produce two complete adult individuals. More dramatic is the ability of adults of species belonging to the triclad genus *Phagocata* to divide into a number of separate fragments, each of which subsequently encysts and develops into a complete adult worm. Their ability to regenerate has made freshwater triclads favored animals for studies in wound healing and developmental genetics. Asexual reproduction in the form of polyembryony occurs in a diversity of free-living groups such as the triclads, rhabdocoels, "lecithoepitheliatans," and rhabdocoels.

With the exception of the aspidogastreans, asexual multiplication is found in at least some members of all of the neodermatan groups. Although it is uncommon among the monogeneans, it is considered to be present in the form of sequential polyembryony (hyperviviparity) in some members of the order Gyrodactylidea. Rather than releasing eggs containing oncomiracidia, an adult can produce a second generation juvenile *in utero* (without sexual reproduction) that in turn can produce a third generation juvenile *in utero*, until one single individual may yield in excess of 20 individuals of the subsequent generation from within its own body, apparently without the intervention of a second individual or of gametes. As a result, the body of such asexually multiplying individuals in effect resembles a series of Russian dolls. There is evidence, however, of sperm in the seminal receptacle of some of these embryos, which has led some to question this as a truly asexual form of multiplication.

Digeneans typically undergo asexual multiplication in the larval stages that parasitize the first, usually molluscan, intermediate host. All digeneans possess one or more generations of sporocysts or one or more generations of rediae, or one or more generations of both sporocysts and rediae. Asexual multiplication occurs in the generation of all larval stages

developing within any generation (mother or daughter) of both sporocysts and rediae. This form of asexual multiplication, termed polyembryony, results in multiple genetically identical individuals of the subsequent larval stage that develop within the saccate body of the parent generation. Thus, first generation sporocysts (mother sporocysts) produce either multiple second generation sporocysts (daughter sporocysts) or multiple first generation rediae (mother rediae), which in turn produce multiple second generation rediae (mother rediae) or multiple second generation rediae (daughter rediae), respectively. Second generation sporocysts produce either multiple cercariae or multiple rediae that then subsequently produce multiple cercariae.

In tapeworms, asexual multiplication occurs in the terrestrial members of the order Cyclophyllidea that develop through larval stages known as coeneri and hydatid cysts. The fluid-filled cavity of these larvae is lined with a layer of germinative tissue that produces multiple protoscoleces, in the case of coeneri, and daughter hydatids that in turn are lined with germinative tissue that produces multiple protoscoleces, in the case of hydatid cysts. Each protoscolex has the potential to become an adult worm. The reproductive potential in these groups is enormous, with the hydatid cysts of some species producing hundreds of thousands, perhaps even millions, of protoscoleces.

Ontogeny

There are a remarkable variety of larval forms found among the platyhelminths, especially within and among the classes of neodermatans. In general, the life cycle of each class of neodermatan (see Figures 71–73) is characterized by one or more unique larval stages (Plate 5). This diversity reflects the great

Figure 71 Generalized monogenean life cycle. (a) Adult on gills of definitive host (usually an aquatic vertebrate), undergoes sexual reproduction, and produces eggs; (b) eggs released into water; (c) oncomiracidium hatches from egg; (d) oncomiracidium finds definitive host.

Figure 72 Generalized digenean life cycle. (a) Adult in definitive host, undergoes sexual reproduction and produces eggs; (b) eggs released with feces of host; (c) miracidium hatches from egg and penetrates first intermediate host (usually a mollusc); (d) miracidium develops into sporocyst containing numerous redia; (e) redia leave sporocyst and produce numerous cercariae; (f) cercaria escapes from first host and finds second intermediate host; (g) cercaria sheds tail, encysts, and develops into metacercaria; (h) second intermediate host containing metacercaria is eaten by definitive host.

Figure 73 Generalized life cycle of aquatic cestode. (a) Adult in definitive host, undergoes sexual reproduction, and produces eggs; (b) eggs released with faeces of host; (c) coracidium larva hatches from egg and penetrates first intermediate host (usually a copepod); (d) coracidium develops into proceroid; (e) first host eaten by second intermediate host; (f) proceroid develops into plerocercoid; (g) second host eaten by definitive host (usually a piscivorous mammal).

range of habitats invaded and life history strategies employed. Most non-neodermatans undergo direct development such that the zygote develops directly into a form resembling a young adult. As discussed by Ruppert (1978), however, there are several notable exceptions to this pattern. One species of catenulid develops from a zygote into a pelagic larval stage known as a Luther's larva (Figure 74, Plate 5); the larva is vermiform in shape, ciliated throughout, but in addition possesses several anterior rings of elongate cilia that aid in swimming. The zygotes of some polyclads develop into free-swimming, ciliated larval stages bearing arms. These larvae are generally referred to as Götte's larvae (Figure 75, Plate 5) or Müller's larvae (Figure 76, Plate 5) depending on whether they possess four or seven to ten arms, respectively. This variation in developmental pattern is seen among individuals of some polyclad species. Götte's larvae are found only in members of the polyclad suborder Acotylea; Müller's larvae are known from members of both suborders of polyclads. There does not seem to be a phylogenetic pattern to the distribution of these larval stages among the polyclads. For example, the polyclad genus *Stylochus* includes species that develop into Götte's larvae, species that develop into Müller's larvae, and species that undergo direct development.

In general, the monogenean life cycle consists of two stages, the adult and a free-swimming larva, which is usually ciliated, known as the oncomiracidium. This larva usually possesses one or two pairs of ocelli, and is conspicuous in its possession of a posterior attachment structure known as a haptor, which is usually armed with hooklets (uncinuli) and sometimes also with hamuli (Figure 77, Plate 5). The oncomiracidium differs from the ciliated larvae of other neodermatans in that its cilia are often restricted to three distinct regions. When the oncomiracidium hatches from an egg, which is sometimes anchored to the substrate, it swims or creeps to find its vertebrate host. An oncomiracidial stage is mostly lacking from monogeneans such as the gyrodactylideans, which are unusually in that they are generally viviparous and undergo sequential polyembryony. A generalized oviparous monogenean life cycle is shown in Figure 71.

Prior to developing into the adult form, aspidogastreans pass through a larval stage called a cotylocidium (Figure 78, Plate 5), which is often but not always ciliated. This larval stage is free-swimming in at least some species. However, the life cycles of many species are not yet fully understood. In some cases it appears that the cotylocidium hatches from the egg and parasitizes the same host as the parent individual from which it was released. In other cases it appears that the cotylocidium hatches from the egg and moves into the water column to find a new host. In yet other cases the cotylocidium never hatches from the egg; rather, the egg is ingested by the molluscan host. In some species the life cycle is direct, involving only a single host. In other species, the life cycle may involve a second host which may be infected by ingesting infected molluscs.

Digeneans undergo complex development in which certain life cycle stages are able to produce multiple copies of new generations before becoming sexually reproductive adults. Consequently the term "larva" is used loosely when discussing life cycle stages in the Digenea. The digeneans pass through a series of larval stages that are either parasitic or free-living,

depending on their association with this sequence of hosts. A generalized digenean life cycle is illustrated in **Figure 72**. As can be seen, the basic sequence of larvae is as follows: miracidium, sporocyst, redia, cercaria, and metacercaria. The miracidium (**Figure 79, Plate 5**) possesses cilia on epidermal plates, or occasionally on tufts or bars. The neodermis is formed when the miracidium sheds its epidermal cell plates, thus all stages following the miracidium have an outer layer that is a neodermis. In most taxa the miracidium develops into a sporocyst, but it occasionally may develop into a redia. Sporocysts and redia are both saciform. The main difference between them is that the sporocyst has none of the components of a digestive system (**Figure 80, Plate 5**), whereas the redia usually possesses at least a mouth, a pharynx, and often a single intestinal caecum (**Figure 81, Plate 5**). These stages vary morphologically among species in their possession of lateral lobes, and in some cases birth pores; the sporocysts of some species are branched. It is quite common for digeneans to possess more than a single sporocyst or redial generation in their life cycle. A first generation sporocyst (mother sporocyst) is essentially a miracidium that has lost its epidermal plates, whereas the second generation sporocysts (daughter sporocysts) are produced through asexual multiplication within the primary sporocyst. A first generation redia (mother redia) is most commonly produced through asexual multiplication within a primary or secondary sporocyst, but exceptionally develops directly from a miracidium that has shed its epidermal plates. Second generation rediae (daughter rediae) are produced through asexual multiplication within the primary redia. In most taxa, the final result of several generations of sporocysts or redia is the development of a number of cercariae. Each cercaria generally possesses an anterior body and a posterior tail. The cercaria is by far the most morphologically diverse of the digenean larval forms. Indeed, classification of the digenean families is based to a large extent on cercarial morphology. An elaborate nomenclature based on morphology exists to describe these cercarial types (e.g., see **Cable, 1956**). Examples of some of the more distinctive types include ophthalamoxiphidiocercaria (**Figure 82, Plate 5**), furcocercous (**Figure 83, Plate 5**), microcercous (**Figure 84, Plate 5**), and cystocercous cercariae (**Figure 85, Plate 5**). The metacercarial stage is usually achieved when the cercaria drops its tail and secretes a protective cyst around itself. The metacercaria is essentially a juvenile version of the adult worm (**Figure 86, Plate 5**). However, variations on this general developmental pattern occur: the metacercarial stage may be lacking or it may be preceded by an unencysted mesocercarial stage.

Associations of these larval forms with their hosts are quite predictable. In general, the miracidium and cercaria are free-living forms. The miracidium hatches from the egg and seeks the first (molluscan) host; the cercaria escapes from the mollusc and seeks either the second intermediate or the definitive host. The sporocyst and redial stages generally parasitize the first (molluscan) host. The metacercarial stage encysts either on aquatic vegetation or in or on the tissue of a second intermediate host, which can be either an invertebrate or vertebrate, depending on the digenean species. Exceptions to this general pattern do occur. In some species, the miracidium is not free-swimming; rather, it remains within the egg, which is subsequently eaten by the first host. In some species, the cercaria does not leave the mollusc to swim freely; rather, it continues its development into a metacercaria, encysting within the body of the sporocyst or redia within the molluscan host. In species that lack metacercaria, such as the schistosomes, the cercaria penetrates the tissues of the definitive host directly. This stage is referred to as a schistosomula once it drops its tail and enters the host.

Both amphilinideans and gyrocotylideans possess a ciliated larval stage known as a lycophore larva (**Figure 87 and Figure 88, respectively; Plate 5**). This larva possesses 10 hooks at the posterior end of its body; these hooks are of similar size and shape in gyrocotylideans but consist of six large and four small hooks, which also differ in shape, in the amphilinideans. This larval stage is also sometimes referred to as a decacanth. The life histories of many species in these two cestode groups are not well known. It appears that, in at least some amphilinideans, the lycophore does not escape from the egg until it is eaten by a small crustacean. In this intermediate host, the lycophore burrows through the gut and comes to rest in the hemocoel, where it develops into a proceroid by shedding its ciliated epidermal cells, elongating, and developing a posterior tail. It subsequently develops into a plerocercoid by shedding its tail and undergoing further elongation. In another case, the lycophore larva hatches and actively penetrates through the cuticle of the intermediate crayfish host. Development into the adult stage occurs only when the intermediate host is eaten by an appropriate vertebrate, at which point the plerocercoid sheds its tail and becomes sexually mature. It is possible that gyrocotylideans do not require an intermediate host to complete their development.

Most eucestodes require at least two hosts to complete their life cycles, but it is also common for additional paratenic hosts to occur in the life cycles of these platyhelminths. Paratenic hosts are not required, but serve to bridge food chain gaps,

Plate 5 Larval stages (**Figures 74–94**) 74. Catenulida: Luther's larva (Ruppert, 1977); 75. Polycladida: Götte's larva (Ruppert, 1977); 76. Polycladida: Müller's larva (Ruppert, 1977); **Figure 77**. Monogenea: oncomiracidium; 78. Aspidogastrea: cotylocidum; 79. Digenea: miracidium; 80. Digenea: sporocyst; 81. Digenea: redia; 82. Digenea: ophthalamoxiphidiocercaria; 83. Digenea: furcocercous cercaria; 84. Digenea: microcercous cercaria; 85. Digenea: cystocercous cercaria; 86. Digenea: unencysted metacercaria; 87. Cestoda: gyrocotylidean lycophore larva (Beauchamp in **Grassé, 1961**); 88. Cestoda: amphilinidean lycophore larva (deBeauchamp in **Grassé, 1961**); 89. Cestoda: coracidium; 90. Cestoda: proceroid (Joyeux and Baer in **Grassé, 1961**); 91. Cestoda: cysticercoid (scolex retracted); 92. Cestoda: cysticercus (scolex retracted and invaginated); 93. Cestoda: hydatid cyst 94. Cestoda: plerocercoid. Abbreviations: A, adhesive disc; AC, acetabulum; APO, apical organ; AR, arm; B, brain; BDY, body; BL, bladder; BR, brood sac; CE, cercomer; CR, ciliary ring; CT, ciliary tuft; DC, developing cercaria; DH, daughter hydatid cyst; DR, developing redia; EM, embryophore; EP, epidermal cell; EV, excretory vesicle; EXP, excretory pore; FI, filament; GE, germ cells; GEL, germinal layer; H, hook; HE, hexacanth embryo; HP, haptor; I, intestine; LL, laminated layer; M, mouth; NE, neodermis; NK, neck; OC, ocellus; OS, oral sucker; PEG, penetration glands; PH, pharynx; PN, protonephridium; PRT, protoscolex; RO, rostellum; S, sucker; SC, statocyst; SCO, scolex; SET, setae; ST, stylet; TA, tail.

thereby facilitating infection of appropriate vertebrate hosts. A generalized aquatic eucestode life cycle is illustrated in **Figure 73**. In general, eucestode zygotes initially develop into a larval stage known as a hexacanth embryo (**Figure 89, Plate 5**). This embryo characteristically possesses three pairs of hooks. The hexacanth may or may not be surrounded by a layer termed an embryophore. A hexacanth surrounded by an embryophore is referred to as an oncosphere. An oncosphere in which the outer region of the embryophore is ciliated is referred to as a coracidium and is usually free-swimming. Some cestode hexacanths or oncospheres are surrounded by an egg shell; this shell possesses a cap-like operculum in some groups. A hexacanth enters the first intermediate host either when it is eaten or by actively swimming to and then penetrating this first host. The first intermediate host is an invertebrate in most eucestode groups, but some terrestrial cyclophyllideans utilize vertebrate as first intermediate hosts. The developmental fate of the hexacanth remains to be discovered in many cestode species; this is especially true of the trypanorhynch and tetraphyllideans. However, existing data suggest that, in general, the larval stages that follow the hexacanth vary somewhat in form among the different cestode orders. These forms are generally given different names depending on their morphology. The key features for distinguishing among larval types are the presence or absence of a scolex, the number of scoleces, whether the scolex (or scoleces) is invaginated (turned inside out) or retracted (withdrawn) into the main body of the larva, and whether a cavity known as a primary lacuna is present. Although current terminology does not accommodate all known combinations of these features, some common larval forms are given (see following). For example, procercooids are solid-bodied, lack a scolex, and usually possess a posterior extension of the body considered a cercomer by some (**Figure 90, Plate 5**). Plerocercoids possess a scolex that is neither invaginated nor retracted (**Figure 94, Plate 5**). Cysticercoids possess a conspicuous scolex that is retracted into the tissue of the neck alone, or, in some cases, the neck is then retracted into the main body of the larva (**Figure 91, Plate 5**). Cysticerci possess one (**Figure 92, Plate 5**), or more invaginated scoleces. Cysticerci with multiple scoleces are referred to as either hydatid cysts (**Figure 93, Plate 5**) or coeneri, depending on whether they have the ability to generate daughter cysts or not, respectively. The reproductive potential of hydatid cysts is enormous as each scolex (termed a protoscolex in hydatids) can go on to become either an adult worm or another protoscolex, if released from the original cyst within the first host. The numerous marine eucestode larvae referred to as "*Scolex pleronektes*" or "*Scolex polymorphus*" are likely to be the plerocercoid larvae of tetraphyllideans.

Phylogenetic Relationships

The tree shown in **Figure 1** provides an overview of the current understanding of the phylogenetic relationships among the major platyhelminth groups. The topology of this tree was derived from a combination of molecular analyses (e.g., Lockyer *et al.*, 2003; Willems *et al.*, 2006). The morphological characters that have been mapped onto the tree include

distinguishing characters for some of the major groups as well as characters that potentially support the phylogenetic relationships shown. It is of note that, the Acoelomorpha (Acoela + Nemertodermatida), are no longer considered members of the Platyhelminthes; instead they are considered to be basal bilaterians or even early divergent deuterostomes, perhaps allied with the enigmatic *Xenoturbella*. The phylogenetic relationships of the platyhelminths in general are treated below. Readers are directed to Littlewood and Bray (2001) and Littlewood *et al.* (2004) for more detailed treatments of the phylogenetic relationships of individual groups.

In truth, few unique features (synapomorphies) have been identified for the phylum Platyhelminthes. None of the characters normally used to describe the group (i.e., dorso-ventral flattening, acoelomate, bilateral symmetry) is unique to this group, nor are some of these characteristics (e.g., dorso-ventral flattening) characteristic of all members of the group. A candidate synapomorphy for the phylum is the lack of accessory centrioles from the base of the cilia of the protonephridial flame bulbs, but unfortunately, this feature is visible only with transmission electron microscopy. The lack of sperm flagella is a condition seen in the three most basal platyhelminth orders (i.e., Catenulida, Macrostomida, and Haplopharyngida), but the remaining platyhelminth groups exhibit the much more widespread condition of biflagellated sperm.

Some morphological and recent molecular data appear to confirm the monophyly of many of the major platyhelminth groups but have highlighted the need for further systematic research. Although the nonmonophyly of the non-neodermatan platyhelminths, previously referred to collectively as the "turbellarians," is now well accepted, the relationships among the non-neodermatan platyhelminth orders remain poorly understood. There is general agreement that the catenulids represent the earliest divergent extant lineage of platyhelminths. The members of this order are exceptional in that they have lost their sperm flagellation and possess a single, rather than a paired, protonephridial system; they also possess protonephridia of Type 1 (i.e., with a cap cell, only two cilia, and no canal cell). In addition, the catenulids lack several distinctive features that unite most or all of the remaining platyhelminths as a group referred to collectively as the Rhabditophora. For example, rhabditophorans and catenulids differ in the genetic codes they use to translate mitochondrial protein-coding genes; catenulids share the same mitochondrial code as other protostome invertebrates but rhabditophorans translate AAA as asparagine (usually lysine), and AUA as isoleucine (usually methionine). In addition, whereas most rhabditophorans possess rhabdites and the duogland adhesive system, the catenulids do not. All platyhelminths except the catenulids, macrostomids, and haplopharyngids share a unique arrangement of flagellar microtubules (9 + '1' rather than 9 + 2) in their sperm, which are biflagellated. All of the platyhelminths except most members of these three orders and the polyclads share the possession of an ovary that is heterocellular (rather than homocellular) and thus produce eggs that are ectolecithal (rather than endolecithal). With the exception of the "lecithoepitheliatans," this suite of heterocellular platyhelminths also possesses vitelline and ovarian cells that are arranged in separate organs, rather than combined into a single germinovitellarium. Apart from the fact that the polyclads

possess extensive branching of their intestinal caeca, temnocephalidans generally exhibit a series of anterior tentacles, and triclads exhibit an extra embryonic intestine, robust morphological synapomorphies for the non-neodermatan platyhelminth orders have not been forthcoming. The proseriatans lack the duogland adhesive system, but so do the temnocephalans and neodermatans. Prolecithophorans have lost their rhabdites, but so too have the temnocephalans and neodermatans. The fecampiids have lost their digestive system, but so too have the cestodes. Molecular data support recognition of the Kalyptorhynchia + "Dalyellioida" + Temnocephalida + "Typhloplanida" as a monophyletic group, and, in fact, these four orders have collectively been referred to as the Rhabdo-coela owing to their possession of a distinctive pharynx and barrel-like intestine. These four orders also share protonephridia of Type 3, but this feature is also found in the "leci-thoepitheliatans." Also comprising a group supported by molecular data are the Prolecithophora, Tricladida, and Fecampiida; however, a morphological synapomorphy for this group remains to be identified.

The monophyly of the Neodermata, consisting of the monopisthocotyleans and polyopisthocotyleans (i.e., monogeneans) as well as aspidogastreans, digeneans, and the cestodes, is now among the most well-established aspects of platyhelminth relationships. The neodermatans are characterized by their possession of a unique syncytial outer body layer known as the neodermis, which generally replaces the cellular epidermis, and is shed when the first larval stage encounters the first host. In addition, the sperm of neodermatans is unusual among platyhelminths (except the kalyptorhynchids) in that the two flagella are actually incorporated into the cytoplasm of the sperm, rather than remaining separate. All neodermatans also lack rhabdites and the duogland adhesive system. The neodermatans are obligate parasites, most of vertebrates, at some time during their lives.

All Monogenea exhibit a posterior haptor. They are further unique among the platyhelminths in their possession of a ciliated larval stage known as the oncomiracidium (with the exception of the few viviparous forms) and also of four rhabdomeric ocelli at some point in their lives. However, the union of the two subclasses (Monopisthocotylea and Polyopisthocotylea) in the Class Monogenea is contradicted by molecular phylogenetic analysis of nuclear ribosomal RNA genes, and mitochondrial genomes, depending on the analysis and gene set; these molecular data suggest paraphyly of the monogeneans, with either Monopisthocotylea or Polyopisthocotylea as the earliest divergent neodermatan lineage. Nonetheless, the monophyly of each of these two subclasses appears to be robust. In each case it is supported by morphological features as articulated above and in the most extensive morphological phylogenetic treatment of the group (see Boeger and Kritsky, 2001). The nonmonophyly of the Class as suggested by molecular work may reflect a rapid divergence of the two subclasses rather than lack of support for monogenean monophyly. The interrelationships among the monogenean orders within these two subclasses are also not universally agreed on.

The Aspidogastrea, Digenea, and Cestoda are united by their complex life cycles. The close affinities between the Aspidogastrea and Digenea, collectively referred to by some as the Trematoda, are supported by their possession of epidermal cells in their first larval stage (cotylacidia and miracidia, respectively)

that are separated from one another by portions of the neodermis. In addition, the first or primary host in the life cycle of the trematodes is a mollusc. The Aspidogastrea are unique in their possession of oviducts separated into chambers by septa and also potentially in their possession of neodermal microvilli in the form of hemispherical microtubercles. The Digenea are distinctive in their possession of several unique larval stages, the miracidium, sporocyst, redia, and cercaria. The phylogenetic relationships among the digeneans have been explored relatively recently in both morphological (e.g., Cribb *et al.*, 2001) and molecular (e.g., Olson *et al.*, 2003) contexts, but no higher-level classification scheme is generally accepted. More detailed analysis is required before these relationships can be resolved with any confidence.

There is little doubt that the cestodes are monophyletic. All cestodes lack essentially all elements of the digestive system and exhibit unique extensions of the neodermis called microtriches (Figure 16). The Eucestodes are particularly unusual in that their sperm lack mitochondria. The relationships among the cestode orders, and also the circumscription of some orders, remain controversial despite the fact that this issue has received much recent attention (e.g., Waeschenbach *et al.*, 2007). The recent erection and resurrection of five cestode orders (Bothriocephalidea, Cathetocephalidea, Diphylobothriidea, Litobothriidea and Rhinebothriidea) attests to the active state of cestode phylogenetics. The monophyly of the Tetraphyllidea is particularly problematic; the order is almost certainly not monophyletic even with the recent extraction of the Rhinebothriidea.

Host Associations

It is useful to consider host associations in general terms. The tendencies of platyhelminths to live in association with other organisms are summarized on the tree in Figure 1. One of the most striking aspects of this mapping is that it becomes apparent that all but six of the major platyhelminth groups (catenulids, macrostomids, haplopharyngids, "leci-thoepitheliatans," bothrioplanidans, and kalyptorhynchids) include at least some species that live in association with other organisms. Thus, symbiosis, in its broadest sense, is a widely distributed feature among the platyhelminths. Within the major platyhelminth groups, however, symbiosis varies in its occurrence. Only the neodermatan groups and the temnocephalids consist entirely of obligate symbionts. The dalyelloids and fecampiids are predominantly symbiotic, although a few free-living species are known. The remaining groups (polyclads, proseriatans, triclads, prolecithophorans, and "typhloplanoids") are predominantly free-living, but all of these groups also include at least some species that are symbiotic.

The hosts of almost all of the symbiotic non-neodermatans are invertebrates; molluscs, arthropods, and echinoderms figure prominently in this role. The neodermatans are unlike almost all of the other symbiotic platyhelminths in that they are generally associated with at least one vertebrate host group at some point in their lives. The aspidogastreans are somewhat exceptional in that some species are known only from freshwater clams and snails. However, records of aspidogastreans from the digestive system and its associated organs, in turtles,

elasmobranchs, and teleosts are not uncommon. Although uncharacteristic of the group as a whole, some monogeneans (e.g., gyroductylids) are found associated with cephalopods, and others with crustaceans that parasitize teleosts or elasmobranchs.

With the exception of the monogeneans, the neodermatan groups are also unique in that their life cycles generally involve more than a single host species. All digeneans possess at least two different hosts in their life cycles. In general, the first (intermediate) host is a mollusc, while the final (definitive) host is a vertebrate. In species possessing life cycles involving more than two hosts, there is one (or sometimes more) additional intermediate (or paratenic) host that is either an invertebrate or a vertebrate depending on the digenean group. In such taxa the host that precedes the vertebrate is generally an invertebrate, often some sort of mollusc or arthropod. The monogeneans are exceptional in this respect as their life cycles involve only a single host.

Symbiotic platyhelminths are found either in or on their hosts. The non-neodermatan groups are often found on, rather than in, their hosts. The exceptions are the fecampiids, "dalyelloids," which are most commonly found inhabiting the coelom or digestive tract of their hosts. Among the neodermatans, the monogeneans are unique in that they are generally found on (i.e., ectoparasitic), rather than in, their hosts whereas the remaining neodermatan groups are most commonly found as endoparasites of their respective hosts.

Medical Importance

The medical and economical importance of the various platyhelminth groups is closely tied to the type and intimacy of the host associations of the groups. Species that use vertebrates as hosts are obviously of much greater concern to humans than those that do not. Thus, the neodermatans are by far the most medically and economically important platyhelminth groups. Space limitations do not permit discussion of the economic consequences of infections with neodermatans, but some of the medically important species are briefly discussed below.

Within the neodermatans only the digeneans and cestodes include species that infect humans. Among the 25 superfamilies of digeneans, human parasites are essentially restricted to four. In the majority of these species it is the adult stage that parasitizes humans. Many of these species are zoonotic; that is, their normal hosts are usually vertebrates other than humans. Humans acquire infections with such species when they unwittingly ingest the metacercarial stage. These zoonotic groups infect a variety of different organs in their human hosts. They include a total of eight species of lung digeneans in the superfamily Gorgoderioidea, five species of liver digeneans in the superfamily Opisthorchioidea, and seven species in the superfamilies Echinostomatoidea, Opisthorchioidea, and Gorgoderioidea that inhabit the digestive tract of their hosts. Finally, human infection with cercariae of species of the superfamily Schistosomatoidea that normally infect birds and aquatic mammals is responsible for an irritating skin condition in humans known as cercarial dermatitis or swimmer's itch.

Only six species of digeneans parasitize humans as their normal final (definitive) hosts. These include one species of liver fluke in the superfamily Opisthorchioidea and five species of blood flukes in the superfamily Schistosomatoidea. The unusual life cycle of the schistosomes requires that humans come into contact with the free-swimming cercariae of these species to acquire an infection. Schistosomes, which cause a disease known as schistosomiasis in humans, are without question the most deadly of the digeneans. Hundreds of millions of people globally are infected with these species. Schistosomes are responsible for the deaths of tens of thousands of people each year.

Species that parasitize humans belong to only two of the 18 orders of tapeworms. The adults of at least four species of diphyllbothriideans (all of which are members of the genus *Diphyllbothrium*) have been reported from the digestive system of humans; evidence suggests that all of these species are zoonotic in humans, as they normally parasitize other fish-eating vertebrates as adults. Plerocercoids of some species of diphyllbothriideans of the genus *Spirometra* are known to parasitize the musculature and subcutaneous tissues of humans, causing a condition known as sparganosis. By far the most pathogenic of the human tapeworms, however, are the cyclophyllideans. Nine species in five genera parasitize humans. These species are known from humans as either larval or adult stages. Larval stages are generally much more pathogenic than adult stages. The hydatid cysts, coeneri, and cysticerci of *Echinococcus*, *Multiceps*, and *Taenia* species, respectively, are arguably the most life-threatening of the human-infecting cestodes. These larval stages often develop in difficult-to-treat extraintestinal sites, such as the brain, or grow extremely large and, in some cases, invasively into one or more organs of the body, making surgical removal of the parasite difficult. Thus, infection with any of these larval stages can be fatal. Infection with an adult tapeworm is generally debilitating rather than life-threatening, because these stages remain in the digestive system and thus are relatively easy to treat. With the exception of *Taenia solium*, it appears that tapeworm infections in humans are also all zoonotic. Infection with adult tapeworms can be prevented by properly cooking food. Infection with larval stages usually involves contact with fecal matter from humans or other animals.

Glossary

Acidophiles From the Latin *acidus* (sour) and the Greek *philos* (loving). Includes organisms that grow optimally at low pH.

Archaea One of three domains of life. From the Greek *archaios* (ancient, primitive). Prokaryotic cells; formerly called Archaeobacteria.

Bacteria One of three domains of life. From the Greek *bakterion* (staff, rod). Prokaryotic cells; formerly called Eubacteria.

Crenarchaeota One of two kingdoms of organisms of the domain Archaea. From the Greek *crene* (spring, fountain), for the resemblance of these organisms to the ancestor of the Archaea, and *archaios* (ancient). Include sulfur-metabolizing, extreme thermophiles.

Eukarya One of three domains of life. From the Greek *eu* (good, true) and *karion* (nut; refers to the nucleus). Eukaryotic cells; formerly called Eucaryotes.

Euryarchaeota One of two kingdoms within the domain Archaea. From the Greek *eury*s (broad, wide), for the relatively broad patterns of metabolism of these organisms, and *archaios* (ancient). Includes halophiles, methanogens, and some anaerobic, sulfur-metabolizing, extreme thermophiles.

Halophiles From the Greek *halos* (salt) and *philos* (loving). Includes organisms that grow optimally at high salt concentrations.

Hyperthermophiles From the Greek *hyper* (over), *therme* (heat), and *philos* (loving). Includes organisms that grow optimally at temperatures higher than 80 °C.

Korarchaeota Proposed third kingdom within the domain Archaea. From the Greek *koros* (young man), for the early divergence of this group during the evolution of the Archaea, and *archaios* (ancient). Includes a small group of ribosomal RNA sequences retrieved from geothermally heated sediments.

Mesophiles From the Greek *mesos* (middle) and *philos* (loving). Includes organisms that grow optimally at temperatures between 20 and 50 °C.

Methanogens Strictly anaerobic Archaea that produce (Greek *gen*: to produce) methane.

Phylogeny The study of the evolutionary relationships among organisms or genes.

Ribosomal rRNA Universally distributed molecule among cellular life forms. Widely used to infer the evolutionary relationships among organisms.

Thermophiles From the Greek *therme* (heat) and *philos* (loving). Includes organisms that grow optimally at temperatures between 50 and 80 °C.

Introduction

Historical Background

For more than 50 years, the notion that there were two basic kinds of living organisms, prokaryotes and eukaryotes, was generally accepted. The placement of a specific organism within one or the other group was based on overall morphological and phenotypic similarities. In 1965, Zuckerkandl and Pauling for the first time suggested that sequences of molecules could be used to reconstruct evolutionary history. Thus, they opened the way to molecular phylogeny, a discipline that studies the evolutionary relationships among organisms or genes. Using molecular phylogeny, in the late 1970s Carl Woese and co-workers found evidence that life consisted not of two but of three distinct groups of organisms: eukaryotes and two kinds of prokaryotes, the Eubacteria and the Archaeobacteria. Their evidence was based on the phylogenetic analysis of a single molecule, the small-subunit ribosomal RNA (SSU rRNA), which is now generally considered an excellent molecule for studying the evolutionary relationships among organisms. The tripartite view of life was formally proposed by Woese *et al.* in 1990 in the form of three domains: the Eucarya

(formerly Eukaryotes), Bacteria (formerly Eubacteria), and Archaea (formerly Archaeobacteria).

Although Archaea resemble Bacteria morphologically, they differ in a variety of cellular and genetic features. From a cellular and biochemical standpoint, Archaea have some unique characteristics, such as the composition of their cell wall and membranes. From a genetic standpoint, Archaea have a unique combination of characteristics once thought to be exclusive to either the Bacteria or Eucarya. Recent analysis of genomic sequences revealed that there is a tendency for archaeal genomes to be “grab-bags” or chimeras of both bacterial and eukaryotic sequences.

Since many Archaea thrive under unusual environmental conditions that are lethal to most organisms, such as high temperature, high salinity, or extreme pH, they provide experimental models to study adaptations to extreme environments. From an evolutionary standpoint, the study of modern Archaea may offer valuable insights into the nature of the evolution of biological processes and the origin of life.

Taxonomy and Phylogeny

Molecular phylogenetic studies involving the comparison of SSU rRNA sequences revealed that the domain Archaea

consists of two kingdoms: the Crenarchaeota and the Euryarchaeota (Figure 1). Physiologically characterized members of the Crenarchaeota include extremely thermophilic microorganisms belonging to the order Thermoproteales (e.g., *Thermoproteus* and *Pyrobaculum*) and to the proposed order Igneococcales (e.g., *Pyrodictium* and *Desulfurococcus*), respectively, and thermoacidophilic microorganisms belonging to the order Sulfolobales (e.g., *Sulfolobus* and *Acidianus*). The Euryarchaeota comprise a metabolically versatile group, which includes all the methanogenic Archaea (orders Methanopyrales, Methanococcales, Methanobacteriales, Methanomicrobiales, and Methanosarcinales), the extreme halophiles (order Halobacteriales), the extreme thermophiles (orders Thermococcales and Archaeoglobales), and the extremely acidophilic microorganisms belonging to the order Thermoplasmatales.

The recent application of molecular approaches to survey microbial diversity in natural environments has provided a new perspective on the distribution and evolutionary relationships of the Archaea. A small group of SSU rRNA sequences retrieved from geothermally heated sediments were found to be different enough from all other archaeal rRNA sequences to warrant the proposal of a new kingdom within the Archaea, namely, the Korarchaeota (see Figure 3). Furthermore, the Crenarchaeota, once thought to be restricted to high-temperature environments, have been found to be ubiquitously distributed, challenging earlier evidence that these microorganisms were confined to high-temperature ecological niches.

Diversity, Ecology, and Physiology of the Archaea

In general, the Archaea fall within three general physiological types: (i) thermophiles that live at high temperatures (some thermophiles are adapted to live in extremely low pH conditions and are known as thermoacidophiles); (ii) methanogens that inhabit strictly anaerobic environments and convert carbon dioxide and simple organic molecules to methane; and (iii) halophiles that inhabit highly saline environments and are characterized by a chemoorganotrophic, aerobic metabolism. These three major groups of Archaea are adapted to live in unusual environments and are commonly known as extremophiles. However, molecular surveys have recently revealed that Archaea are much more diverse than previously known, and that they are also widespread in more common biotopes. Non-extremophilic Archaea have been found in marine plankton, terrestrial soils, and freshwater and marine sediments. Because these newly discovered Archaea have resisted cultivation to date, their physiology and metabolic potential are unknown.

Thermophilic Archaea

Extremely thermophilic Archaea, or hyperthermophiles, comprise a group of microorganisms which are adapted to grow at temperatures higher than 80 °C. Hyperthermophilic Archaea are generally restricted to environments in which geothermal energy is available, such as hot springs,

solfataras, geothermally heated marine sediments, and submarine hydrothermal vents. These environments are rich in sulfur and sulfides, and consequently many of the thermophiles have a sulfur-dependent metabolism. Extremely thermophilic Archaea can carry out a variety of respiratory processes and in most cases elemental sulfur is used as either an electron donor or an electron acceptor. Elemental sulfur is formed from geothermal H₂S either by spontaneous oxidation of H₂S with O₂ or through the reaction between H₂S and SO₂. Submarine volcanic environments include shallow (2–50 m) and deep-sea hydrothermal vents (to depths exceeding 3700 m), where the pressure, even at shallow depths, can raise the boiling point of water sufficiently to select for organisms capable of growth at temperatures higher than 100 °C.

Among the Crenarchaeota, *Pyrodictium* and *Pyrolobus* (order Igneococcales) are chemolithotrophic sulfur-dependent hyperthermophiles whose maximum growth temperatures of 110 and 113 °C, respectively, represent the upper temperature limits for life known so far. *Pyrodictium* is a strict anaerobe and grows on H₂ and S⁰. *Pyrolobus* is unusual in that it is capable of reducing both NO₃⁻ and S₂O₃²⁻ to NH₄⁺ and H₂S, respectively, with H₂ as the electron donor. *Desulfurococcus* and *Staphylothermus* (order Igneococcales) are phylogenetically clearly separate from the *Pyrodictium* group (Figure 1). These coccoid or disc-shaped organisms have an optimal growth temperature higher than 85 °C and, in contrast with the *Pyrodictium* group, a maximum temperature not higher than 100 °C. They can grow chemolithoautotrophically by sulfur reduction to H₂S or heterotrophically by sulfur respiration of various organic substrates. *Thermoproteus* and *Thermofilum* (order Thermoproteales) are rod-shaped hyperthermophiles that grow in mildly acidic conditions at temperatures up to 95 °C. They are both strict anaerobes that can grow chemolithotrophically on H₂ or chemoorganotrophically on complex carbon substrates with S⁰ as an electron acceptor. *Pyrobaculum aerophilum* (order Thermoproteales) is a rod-shaped hyperthermophile capable of aerobic respiration in the presence of very low oxygen concentrations (~0.3%) and nitrate reduction under strictly anaerobic conditions.

Solfataras are terrestrial volcanic environments which abound in sulfur and are gassed by emanating steam carrying CO₂, H₂, and H₂S, with temperatures up to 100 °C. Thermoacidophilic members of the order Sulfolobales inhabit acidic solfataras and oxidize H₂S or S⁰ to H₂SO₄ using organic carbon or fixing CO₂ as a carbon source. *Sulfolobus* grows at, or close to, the surface of acidic solfataras at temperatures between 75 and 85 °C and low pH. No thermoacidophilic, aerobic sulfur oxidizers of the *Sulfolobus* type have been isolated from deep-sea hydrothermal vents. This is related to the steep gradient that occurs between the rising hot, anoxic hydrothermal fluid and the cold, oxygenated ambient sea water, which does not provide an ideal niche for these type of organisms. *Acidianus* (order Sulfolobales) is a close relative of *Sulfolobus* that grows at an optimum temperature of 85 °C and pH 2. *Acidianus* is a more versatile organism than *Sulfolobus* in that it is capable of growth under both aerobic and anaerobic conditions. During aerobic growth, S⁰ is oxidized to H₂SO₄, whereas under anaerobic conditions H₂ is oxidized and S⁰ is concomitantly reduced to H₂S.

Figure 1 Unrooted phylogenetic tree showing the relationships among representative species of Archaea. Branch lengths (indicated by horizontal distances from nodes) are proportional to the evolutionary distances determined by comparative analyses of SSU rRNA sequences. The scale represents the expected number of changes per sequence position.

Among the Euryarchaeota, *Pyrococcus* and *Thermococcus* (order Thermococcales) are two closely related, coccoid, sulfur-reducing hyperthermophiles that differ primarily in their optimal growth temperatures (100 and 88 °C, respectively) (Figure 2). These organisms are obligate anaerobic chemoorganotrophs that utilize proteins and other complex organic mixtures and reduce S^0 to H_2S . *Archaeoglobus* (order Archaeoglobales) is an extremely thermophilic, sulfate-respiring organism which has been isolated from shallow and deep-sea hydrothermal environments. *Archaeoglobus* grows at temperatures up to 95 °C using H_2 , lactate, or complex organic mixtures as electron donors and reducing SO_4^{2-} and $S_2O_3^{2-}$ to H_2S . *Ferroplasma* (order Archaeoglobales) is a coccoid, hyperthermophilic organism capable of oxidizing Fe^{2+} at neutral pH under anoxic conditions.

The order Thermoplasmatales includes two moderately thermophilic organisms (optimum temperature growth approximately 60 °C), *Thermoplasma* and *Picrophilus*, isolated from coal refuse piles and acidic solfataras. *Thermoplasma* is an acidophilic, cell wall-less Archaeon that resembles bacterial *Mycoplasma* species. It can grow aerobically and anaerobically. Under anaerobic conditions there is a requirement for S^0 , which is reduced to H_2S .

Picrophilus is an extremely acidophilic, heterotrophic organism adapted to grow optimally at pH 0.7. Table 1 summarizes some characteristics of the thermophilic Archaea.

Methanogenic Archaea

Methanogenic Archaea are characterized by their metabolic capability of producing methane. Methanogenesis is a strictly anaerobic respiratory means of metabolism that produces cellular energy in the form of ATP through the reduction of carbon dioxide, formate, or CO (CO₂-reducing methanogens), methanol or methylamines (methylotrophic methanogens), or acetate (acetoclastic methanogens), respectively, to methane. Typical methanogenic reactions are

Most methanogens are capable of autotrophic growth using molecular hydrogen to reduce CO₂ in a multistep reaction that requires coenzymes unique to this group of

organisms, such as methanofuran, methanopterin, F_{420} , F_{430} , and coenzyme M. Methanofuran is a low-molecular-weight phenol derivative involved in the first step of methanogenesis. Methanopterin is a pterin-containing coenzyme which resembles the vitamin folic acid and serves as a Cl carrier during

the reduction of CO_2 to CH_4 . Coenzyme F_{420} is a flavin derivative involved in redox reactions. The oxidized form of F_{420} has a characteristic blue-green fluorescence at 420 nm and is very useful in recognizing methanogens microscopically. Coenzymes M and F_{430} play a crucial role in the final step of the

Table 2 General characteristics of methanogenic Archaea

Order Genus	Morphology	Substrates	Temperature (°C)
Methanobacteriales			
<i>Methanobacterium</i>	Long rods	H ₂ + CO ₂ , formate	35–40
<i>Methanobrevibacter</i>	Short rods	H ₂ + CO ₂ , formate	30–38
<i>Methanosphaera</i>	Cocci	Methanol + H ₂ (both needed)	36–40
<i>Methanothermus</i>	Rods	H ₂ + CO ₂	83–88

methanogenesis as part of the methyl reductase system. F₄₃₀ is a yellow, soluble, nickel-containing tetrapyrrole that, unlike F₄₂₀, does not fluoresce.

All methanogenic Archaea are strictly anaerobic and occupy anoxic habitats, such as sediments, marshes, waterlogged soils, submarine hydrothermal vents, and the digestive tracts of animals. Methanogens are usually abundant in environments depleted in Fe³⁺, NO³⁻, and SO₄²⁻ because these substrates stimulate growth of anaerobic bacteria that can outcompete them. Therefore, methanogenesis is usually limited in sulfate-rich marine environments because the methanogens have to compete with sulfate-reducing bacteria for H₂. Since oxidation of H₂ with sulfate as the electron acceptor is thermodynamically more favorable than when CO₂ is the electron acceptor (as in methanogenesis), sulfate reducers are usually favored. However, since methylotrophic methanogens can use noncompetitive substrates (such as methylamines, which are inaccessible to sulfate-reducers), they can be detected in some sulfate-rich environments. Most methanogens have been found to contain the nitrogenase protein complex; therefore, they are also capable of anaerobic nitrogen fixation under certain growth conditions.

The methanogenic Archaea is a diverse group with many species; it is the largest taxonomic group of Archaea. The order Methanobacteriales includes mainly rod-shaped methanogens that grow by CO₂ reduction, although a few species of the genus *Methanosphaera* are cocci that grow only by using H₂ to reduce methanol to methane. *Methanobrevibacter* species are very short rods which use H₂ or formate to reduce CO₂ to CH₄. The genus *Methanothermus* includes extremely

thermophilic methanogens isolated from terrestrial geothermal springs. They can grow at 88 °C on CO₂ and H₂.

The order Methanomicrobiales encompass a genetically diverse group of CO₂-reducing methanogens that grow at temperatures ranging from 30 to 60 °C.

The order Methanosarcinales includes morphologically diverse organisms such as *Methanosarcina*, which form irregular spheroid bodies occurring alone or in aggregates of cells, and *Methanotherix*, which forms sheathed rods. Both *Methanotherix* and *Methanosarcina* are acetoclastic methanogens, although the latter can also use methanol and methylamines as substrates for methanogenesis.

The order Methanococcales includes mesophilic and extremely thermophilic methanogens characterized by irregular coccoid morphology. *Methanococcus jannaschii* was isolated from a deep-sea hydrothermal vent system where it grows at 88 °C on CO₂ and H₂ released in volcanic gases.

Methanopyrus (order Methanopyrales) is an extremely thermophilic methanogen isolated from hydrothermally influenced sediments, and it is capable of autotrophic growth at temperatures up to 110 °C. Table 2 summarizes some characteristics of the methanogenic Archaea.

Halophilic Archaea

The halophilic Archaea occur in environments characterized by high salinity. Salt-neutral lakes, saline soils, solar evaporation marine salterns (areas where sea salt is produced), and subsurface haline deposits are among the most common habitats for halophiles. Most of the halophilic Archaea are

Table 3 Habitat and general characteristics of halophilic Archaea

Order Genus Species	Habitat	Morphology	Physiological characteristics
Halobacteriales			
<i>Halobacterium</i>		Rod-shaped	
<i>H. Salinarum</i>	Salted fish, hypersaline lakes		Amino acids, phototrophic
<i>Haloferax</i>		Rod/disk-shaped	
<i>H. mediterranei</i>	Salterns		Carbohydrates
<i>H. denitrificans</i>	Salterns		Nitrate respiration
<i>Halorubrum</i>		Rod-shaped	
<i>H. lacusprofundi</i>	Deep lake, Antarctica		Carbohydrates
<i>H. sodomense</i>	Dead Sea		Phototrophic
<i>Haloarcula</i>		Pleiomorphic	
<i>H. vallismortis</i>	Death Valley		Carbohydrates
<i>H. marismortui</i>	Dead Sea		Nitrate respiration
<i>Halococcus</i>		Cocci	
<i>H. morrhuae</i>	Dead sea		Amino acids, Nitrate respiration
<i>H. saccharolyticus</i>	Salterns		Carbohydrates
<i>Natronobacterium</i>		Rod-shaped	
<i>N. gregoryi</i>	Soda lakes		Organic acids, pH 9.5–10
<i>Natronococcus</i>		Cocci	
<i>N. occultus</i>	Soda lakes		Amino acids, pH 9.5–10
<i>Natrialba</i>		Rod-shaped	
<i>N. Asiatica</i>	Sea sand		Nonpigmented, extreme halophile

red or orange because of the presence of carotenoid pigments in the cell envelope. Frequently, due to their abundance, they impart a red color to the brine. Alkaliphilic halophiles are found in soda lakes, which are highly alkaline environments whose high pH (8 to >12) is due to high levels of carbonate. Halophiles require at least 1.5 M NaCl for growth, and optimal salt concentrations are usually in the range of 2–4 M NaCl.

Neutrophilic and alkaliphilic halophiles both belong to the order Halobacteriales. The members of the neutrophilic group, represented by the genera *Halobacterium*, *Halococcus*, *Haloarcula*, and *Haloferax*, grow optimally under conditions of high magnesium and sodium concentrations (0.5 and 4.0 M, respectively) at pH ranging from 5 to 8. Alkaliphilic halophiles (genera *Natronobacterium* and *Natronococcus*) grow optimally at low magnesium concentrations and pH of approximately 10.

Halophilic Archaea have evolved several physiological adaptations that permit their growth in habitats with salt concentrations that cause cellular dehydration and protein denaturation in other organisms. Halophilic Archaea such as *Halobacterium* resist high salt concentrations by pumping large amounts of K⁺ from the environment into the cell such that the concentration of K⁺ inside the cell is greater than the concentration of Na⁺ outside the cell. This mechanism allows *Halobacterium* to remain in positive water balance and avoid dehydration.

The halophilic Archaea are aerobic and grow heterotrophically using carbohydrates, alcohols, organic acids, and amino acids. *Halobacterium* species are normally aerobic but can grow anaerobically in the presence of light. Under oxygen-limiting conditions and in the presence of light, *Halobacterium* inserts large amounts of a protein called bacteriorhodopsin into the cytoplasmic membrane. This purple pigment, which adsorbs light strongly at approximately 570 nm, acts as a light-

driven proton pump and leads to the establishment of an electrochemical membrane potential. Its equilibration can be accompanied by the generation of ATP. Thus, bacteriorhodopsin facilitates a special kind of photophosphorylation. The energy obtained by this mechanism complements that obtained from aerobic substrate oxidation. Table 3 summarizes some characteristics of the halophilic Archaea.

Nonextremophilic Archaea

The application of SSU rRNA-based molecular techniques to survey natural microbial populations has recently revealed that Archaea are virtually ubiquitous. Therefore, our view of the Archaea as highly specialized microorganisms adapted to survive in extreme environments is gradually changing to that of a very diverse group of organisms, including more moderate representatives.

Non-extremophilic Archaea have been identified in a variety of environments, such as temperate and cold marine planktonic habitats, freshwater sediments, soils, terrestrial subsurface environments, and permanently cold deep-sea sediments, and in association with several marine metazoans. To date, none of the non-extremophilic Archaea have been isolated in pure culture; therefore, their phenotypic and physiological characteristics remain unknown. However, their ubiquitous distribution and high phylogenetic diversity suggests a wide range of ecological and physiological adaptations.

The distribution and phylogenetic affiliation of the non-extremophilic Archaea are summarized in Table 4.

Origin and Evolution of the Archaea

Archaea occupy a pivotal phylogenetic position between the two other domains of life, Bacteria and Eukarya (Figure 3).

With the recent sequencing of the entire genomes of several Archaea, it has become evident that archaeal genomes share bacterial and eukaryotic features. Furthermore, the availability of an increasing number of gene sequences from organisms

Table 4 Distribution and phylogenetic affiliation of nonextremophilic Archaea

Distribution	Phylogenetic affiliation
Marine Habitats	
Surface and deep waters (up to 3000 m)	<i>Crenarchaeota</i> , <i>Euryarchaeota</i>

belonging to the three domains of life allows the identification of a “universal” set of protein families present in all three domains. This universal set of proteins can then be used as an estimate of the genome content and the cellular processes that were present in the last universal ancestor of living organisms. However, factors such as horizontal gene transfers between distantly related groups and gene loss make it difficult to draw conclusions about the biology of the last universal ancestor, and different theories have been proposed.

The following sections describe different traits of the Archaea which can be used to infer some properties of the last universal ancestor as well as to provide insights of the origin and evolution of the Archaea.

Early Respiratory Processes

The presence of genes encoding for homologous proteins in organisms belonging to both domains Archaea and Bacteria allows for the reconstruction of cellular processes that were present early in the history of life on Earth. In particular, terminal oxidases belonging to oxygen, nitrate, sulfate, and sulfur respiratory pathways are present in both domains.

Cytochrome oxidase, which catalyzes the reduction of oxygen to water and acts as a redox-linked proton pump, is the key enzyme of aerobic metabolism. This enzyme is present in members of both the Crenarchaeota (*Sulfolobus*, *Acidianus*, and *Pyrobaculum*) and the Euryarchaeota (*Halobacterium* and *Natronobacterium*) as well as in many thermophilic Bacteria (e.g., *Thermus* and *Aquifex*). It is plausible that in the early atmosphere, prior to the advent of oxygenic photosynthesis, microaerophilic organisms similar to the present-day archaeon *Pyrobaculum* may have been able to thrive under extremely low oxygen concentrations, known to have existed as a result of the photolysis of water.

The ability to use sulfate as a terminal electron acceptor is a characteristic common to many mesophilic and thermophilic

Figure 3 Schematic representation of the rooted “universal” SSU rRNA phylogenetic tree showing the position of the Archaea relative to the Bacteria and the Eukarya.

bacterial species and to the thermophilic archaeon *Archaeoglobus*. In addition, a sulfite reductase-type protein has been identified in *Pyrobaculum*. The enzyme dissimilatory sulfite reductase catalyzes the six-electron reduction of (bi)sulfite to sulfide, which is the central energy-conserving step of sulfate respiration. Phylogenetic evidence suggests an ancestral origin of sulfate respiration, a finding which is consistent with the notion that sulfates of magmatic origin were common in the Archaean time. In addition to sulfate reduction, *Archaeoglobus* produces very small quantities of methane. Factor F₄₂₀ and methanopterin, two coenzymes involved in methanogenesis, are also present in *Archaeoglobus*, although this organism appears to lack other cofactors normally present in methanogens. This apparently intermediate type of metabolism between methanogenesis and sulfur reduction suggested that *Archaeoglobus* may represent a transitional form in the diversification of Archaea from sulfur-respiring to methane-producing and halophilic Archaea. The branching position of *Archaeoglobus* in the SSU rRNA tree is consistent with this interpretation (Figure 1).

Sulfur respiration has also been proposed to be an ancestral mode of energetic metabolism on the base of two considerations: (i) Volcanic-derived S⁰ was probably one of the most abundant electron acceptors in the early atmosphere, and (ii) the capacity to reduce S⁰ to H₂S is common among anaerobic, hyperthermophilic members of both Archaea and Bacteria.

Adaptive Features to High Temperature

Archaea exhibit a strong adaptive capacity to extremely high temperatures. Since microorganisms are isothermal, they have to develop strategies to avoid thermal stress. Thus, in order to survive at temperatures in excess of 100 °C, hyperthermophiles have to adapt their cell inventory to function optimally at the temperatures in the niches they occupy. Many different mechanisms have been hypothesized by which hyperthermophiles can simultaneously retain stability and plasticity at high temperatures.

One important mechanism of thermoadaptation is the biosynthesis of thermostable proteins and enzymes that maintain sufficient structural integrity to allow optimal catalytic efficiency at high temperatures. Thermostable proteins are often characterized by a very efficient packing density in the hydrophobic core of the molecule as well as by shorter connecting elements (loops) between regions of secondary structure. An elevated number of ionic interactions has frequently been found in highly thermostable proteins. Ionic interactions among monomers are thought to stabilize multimeric proteins at high temperatures. Overall, these characteristics lead to decreased flexibility in the polypeptide chain, a required feature that compensates for increased thermal fluctuations at high temperatures.

Most living beings need the strand-opening potential of negative DNA supercoiling to allow transcription and other DNA-dependent processes. In bacterial nucleoproteins and in eukaryal chromosomes, DNA has a negative superhelicity as a result of topoisomerase activity and wrapping of DNA around histone cores, respectively. Histone-like proteins may play an important role in certain thermophilic Archaea, protecting

DNA against thermal denaturation and degradation. The DNA-binding proteins isolated from both *Thermoplasma acidophilum* and *Methanothermus fervidus* stabilize double-stranded DNA molecules *in vitro* by increasing their melting temperatures. A novel class of topoisomerases has been identified in both hyperthermophilic Archaea (e.g., *Sulfolobus*) and Bacteria (e.g., *Thermotoga*). Since these enzymes catalyze positive supercoiling into the DNA, they have been referred to as reverse gyrases. Reverse-gyrase activity is widely distributed in hyperthermophiles and appears to be, at least at critical regions, a requirement to prevent DNA denaturation at high temperatures. Thus, the reverse girase may be considered as an ancestral trait retained by present-day hyperthermophilic Archaea.

Evolution

Hyperthermophilic Archaea have been proposed as analogs for the early life on Earth. If life arose and evolved under high-temperature, reduced, sulfur-rich conditions, then the requirement of thermophilic Archaea for high temperature environments as well as their predominantly anaerobic, sulfur-metabolizing phenotype suggest they are good analogs to test such a theory. Two independent lines of evidence suggest that the phenotype of the extant hyperthermophiles may represent remnants of the ancestral Archaea. First, the hyperthermophilic trait is the only one found in both archaeal kingdoms, the Crenarchaeota and the Euryarchaeota. Second, most hyperthermophilic lineages are more slowly evolving than any other archaeal lineage. This is particularly evident when the rate of evolution of the SSU rRNA genes (indicated as the branch length in the phylogenetic tree) is considered (Figure 1). Mesophilic methanogens, halophiles, and the recently discovered non-extremophilic Archaea appear to evolve much faster than hyperthermophiles (Figure 1). Furthermore, mesophilic methanogens, such as members of the Methanococcales, evolve more rapidly than their extremely thermophilic relatives. Therefore, the assumption that more slowly evolving lineages (thermophilic) tend to retain more of the ancestral traits than do rapidly evolving lineages (non-thermophilic) suggests a high-temperature ancestry of the Archaea, which later adapted to lower temperatures.

A different theory supporting a non-thermophilic ancestor to extant life forms has been recently formulated on the base of the strong correlation between the Guanine + Cytosine (G + C) nucleotide content of rRNA genes and the optimal growth temperature of microorganisms. The analysis of rRNA genes from hyperthermophiles suggests that survival in high-temperature conditions requires a high G + C content in rRNA genes. However, the estimated G + C contents of ancestral organisms appeared to be incompatible with life at high temperature and suggested a moderate environmental growth temperature for the universal ancestor. This theory leads to the conclusion that present-day thermophily evolved from mesophilic organisms via adaptation to high temperature.

In principle, the nature of an ancestral organism may be inferred from the distribution of homologous traits among its descendants. However, the reconstruction of early evolutionary histories is complicated by phenomena such as horizontal

gene transfer (gene swapping) among organisms. As new microbial genomes have become available, it has become increasingly evident that extensive gene swapping, even among distantly related organisms, may have occurred. This tends to blur the history of the early stages of life on Earth; therefore, the nature of the last universal ancestor remains elusive. At the same time, comparative functional genomics is providing a new perspective of the characteristics of the universal ancestor. Because of their evolutionary history, Archaea are likely to play a critical role in our understanding of the early events in the evolution of cells and the origin of life.

Glossary

Domains The highest taxonomic rank defined to classify organisms into Archaea, Bacteria, and Eucarya, which differ from each other in fundamental genomic and phenetic properties.

Endosymbiont Specialized form of symbiosis in which one partner thrives within cells, lumen, or tissues of the host organism; most obligate endosymbionts belong to the group of uncultured organisms.

Epigenetic level Study of molecules which are the product of gene expression.

Homology Denoting common ancestry. Structures, processes, sequences, behaviors, etc. are said to be homologous if there is evidence that they are derivations from a common ancestral structure. In molecular biology the term indicates a significant degree of similarity between DNA or proteins.

Phylogeny Natural relatedness among life forms; the science of ordering the genealogy of organisms into a family tree.

Prokaryotes Life forms that are members of the domains Archaea and Bacteria as opposed to Eucarya, comprising organisms with a cell nucleus.

rDNA Genes coding for rRNA that play a fundamental role in the translation process; the most thoroughly studied molecule in prokaryotic cells; used in comparative phylogenetic studies.

Uncultured prokaryotes Organisms, the presence of which has been detected by molecular methods in the environment but they have not been cultured under artificial laboratory conditions.

Recognizing Gaps in Knowledge

Due to progress in methodologies and concepts, facets of biodiversity have not been covered equally in different areas in bacteriology, but progress must be viewed as a logical consequence of available technologies. Introduction of ground-breaking methods is usually followed by a period of increased knowledge in those fields for which the methods were developed. Numerous examples exist in microbiology, such as the elucidation of (i) the ultrastructure of the prokaryotic cell, following the development of the electron microscope; (ii) metabolic and biochemical pathways, following the introduction of the isotope label technique and enzymology; (iii) anaerobic organisms, following the development of appropriate anaerobic cultivation technology; and (iv) cell constituents, following the introduction of the amino acid analyzer, gas chromatography, high-performance liquid chromatography, and thin layer chromatography. Recently, the introduction of high-resolution gel electrophoresis led to one- and two-dimensional fingerprinting methods for proteins,

ribonucleic acids (RNAs), and deoxyribonucleic acids (DNA); application of restriction enzymes, cloning strategies, and polymerase chain reaction (PCR) technology led to improved sequence analysis of genes and genomes; and cloning of PCR fragments of environmental DNA, *in situ* hybridization, and the development of gradient gel electrophoresis revealed a larger spectrum of prokaryotic diversity than previously known. The latter insights have been used to develop strategies in which DNA, isolated from environmental samples, is expressed to yield a spectrum of novel enzymes not detected in strains available from biological resource centers. As a result, taxonomists learned that the vast majority of prokaryotic species are still undetected, and physiologists, biochemists, and geneticists can expect to find novel lines of descent containing organisms that express fundamental deviations from currently known biochemical pathways. New models will help to better understand the structure and function of living matter and the role of prokaryotes in maintaining the biosphere.

The number of validly described species of animals, plants, and lower eukaryotes is approximately 400 times larger than

the number of prokaryotic species (1,600,000 : 4,000). This fraction of bacterial and archaeal species is surprisingly low considering that prokaryotic species evolved eons ago, exploring and occupying any niche that has been investigated for the presence of prokaryotic organisms. Insects, on the other hand, which comprise more than 1 million species, evolved late in evolution—less than 600 million years ago during the Cambium. Certainly, differences in the species definition that exist between the biological species of higher evolved eukaryotes and the pragmatically defined prokaryotic species contribute to the tremendous discrepancy, but it has been shown convincingly that the vast majority of prokaryotic strains which are part of the free-living microbial community species have not been cultured. Endosymbiotic prokaryotes which are not free living but firmly associated with eukaryotic cells are another source of uncultured organisms. The limitation of recognizing the richness of microbial organisms is most likely due to the use of a restricted spectrum of enrichment media which selects for a very narrow spectrum of organisms that compete best under artificial laboratory conditions.

The discussion of diversity issues and the increasing awareness of the importance of microorganisms in maintaining the biosphere is embedded in discussion of the implementation of the articles of the Convention on Biological Diversity (CBD). The driving force behind the CBD has been the recognition of the possibility of a significant reduction or loss of biological diversity at source by human activities, and the preamble admits a general lack of information and knowledge regarding biological diversity. Nowhere is the lack of knowledge more acute than for microbial diversity (prokaryotes, fungi, yeasts, and heterotrophic and autotrophic protists) and there is a widespread appreciation among microbiologists that cultured microorganisms represent a very small, not necessarily ecologically important, fraction of natural microbial diversity.

Considering the total number of nucleotides per genome, far more recognizable diversity can be seen at the molecular level than at the epigenetic level. Compared to the total number of described species, the number of organisms analyzed in genome sequencing projects is still small (about 2.5%), but this portion will increase rapidly and genomic screening and data mining will develop into dominating biological disciplines in the future. However, taxonomists will not lose interest in the more traditional properties of a cell because of the demanding process of describing species and genera. The polyphasic approach to classification requires information about morphology, ultrastructure, metabolism, chemical structure of cell constituents, and genomic features. Thus, from more than 100 years of bacterial classification, an enormous wealth of phenotypic and epigenetic data have accumulated and are of benefit to bacterial taxonomy, which many scientists regard as the mother of biological sciences. However, taxonomists are concerned that this spectrum of diversity will have to be sacrificed for an approach that considers molecular/genomic data more appropriate for delineating taxonomic ranks. Indeed, this cut will happen sooner or later, but it does not mean that the avalanche of genomic data will bury all activities directed toward the elucidation of the phenotype.

Unraveling Phylogenetic Diversity

Whereas the past century unraveled the diversity of epigenetic properties, i.e., those characters that are the result of gene expression, the next century will prove a tremendous wealth of information on genomic properties. The terms genomics and reverse genetics have been coined for the strategy of obtaining value-added information from sequences of genomes and genes. Data mining and meganetworking programs will replace the simple search for similarities between a few homologous genes, and it can be expected that the importance of phenotypic traits will be reintroduced as a consequence of the desire to understand the horizontal and vertical flow of genes and their regulation and expression.

The combination of information of a (small) portion of the genome with phenotypic properties is nowhere exemplified better than in modern classification strategy of prokaryotes. The first component, the backbone of the system, is provided by the primary structure of homologous molecules which have accompanied the organisms since early evolution and they can be ranked according to their evolutionary history. The number and nature of sequence differences among proteins and genes coding for rRNA and proteins allow the recognition of pairs or groups of organisms which evolved from a common ancestor, and the order in which lineages have emerged in time facilitates decisions about the grouping of organisms.

The main problem that has emerged in phylogenetic studies during the past 10 years is the question of whether to place emphasis on the genealogical relationships derived from comparative analyses of a single homologous gene, a gene cluster, or even large parts of the genome. It has been demonstrated convincingly that the historic fate of ribosomal (r)DNA genes does not necessarily represent the fate of other genes because the phylogenetic branching patterns of different genes may show significant deviations. Analysis of the presence and position of genes in completely sequenced prokaryotic and eukaryotic genomes and horizontal gene transfer among genomes with a high plasticity has played an enormous role in designing and shaping early evolved organisms, and the chimerical genomic structure of descendants of early evolving organisms has been proven beyond doubt. The 16S rDNA is the most widely analyzed molecule in phylogenetic studies because of its alternating change of degrees of sequence conservatism that allows the recognition of most distant relationships and moderate and close relationships. The availability of a database comprising more than 10,000 sequences of prokaryotic strains makes it easy to either unambiguously affiliate a new isolate to one of the 4000 species or to postulate the finding of a new taxon in case no highly similar match is obtained with the isolate and a recognized species. Analysis of rDNA is the gold standard for analyzing phylogenetic relatedness; Schleifer and Ludwig (1989) provided excellent evidence that the rDNA data are closely matched by results of comparative analyses of other conservative molecules responsible for central cell functions. Second, the phylogenetic branching patterns provide a scenario in which clusters of related organisms also share a high portion of epigenetic properties. The resolution power of the 16S rDNA is restricted, however, because neither very early

nor very recent evolutionary events are well resolved. Branching patterns are influenced not only by the treeing algorithms applied for inferring phylogenetic relationships but also by the size of the database. A phylogenetic tree is a dynamic construct which will to some extent change its topology with any new sequence added. Consequently, it is difficult for the scientist to judge whether the phylogenetic tree generated is a true reflection of the evolutionary history of the analyzed molecule. If the tree is generated for the purpose of making conclusions on the fate of genomic and epigenetic characteristics of the organisms concerned, conclusions should be underpinned by the analysis of additional evolutionary markers.

Increasingly, genes with a resolution higher than 16S rDNA are sequenced for determining intragenetic and intraspecies relatedness (e.g., genes *hsp65* and *hsp70* coding for heat shock proteins and *gyraseB*). Traditionally, and still required in the polyphasic approach to classification, DNA–DNA hybridization studies are performed at the level of highly related species and at the interspecies level, but the laborious experimental burden and lack of a cumulative database exclude wide application.

Diversity Extends to the Strain Level

In the past, selected physiological reactions and computer-assisted techniques were applied to elucidate intraspecific relationships. This goal can also be achieved by generating patterns from DNA, RNA, and proteins that represent a strain-specific fingerprint or a bar code-type profile. Spontaneous mutations occur at an average rate of about 10^{-7} per gene and generation in prokaryotes but vary to a great extent in genetic loci. The extent to which strains of a species differ from each other also depends on the relative evolutionary time during which strains evolved from each other. Because prokaryotic species are man-made constructs established to facilitate taxonomy, strains included in a species may vary significantly from each other in phylogenetic depth and hence in the extent to which macromolecules diverged. The complexity of the patterns obtained depends on the size, length, and degree of conservatism of the macromolecule of choice and the tools used to cleave, amplify, hybridize, and separate these markers. Separation of DNA fragments by pulsed field electrophoresis, probing of defined genes with labeled probes, visualization of bands via computerized, laser-analyzed densitometer scanning, and the use of fully automated, reproducible techniques have improved the resolution and the monitoring part of the analyses significantly. Pattern identification is rapid, discriminating, and applicable to any species for which DNA, RNA, and whole cell proteins can be isolated. Providing the potential for discrimination, isolates and reference strains that exhibit a high degree of pattern similarity can be considered related. These techniques complement traditional typing methods used mainly in the clinical environment, such as serotyping, biotyping, and phage typing. The decision of whether a strain with a unique pattern actually belongs to a described species or should be described as a new species requires more quantitative methods at the genomic level that allow one to measure the degree of relatedness.

Phylogenetic Diversity and Distribution of Phenotypic Traits

The phylogenetic and phenotypic separation of the domain Archaea from the domains Bacteria and Eucarya (**Figure 1**) is the most exciting result since the introduction of comparative sequence analysis by Woese and Fox in the mid-1970s. The presence of two prokaryotic domains in which members are defined by clearly different genomic and phenotypic properties has changed fundamentally the hypothesis on the dichotomy of life forms and revolutionized ideas about the evolution of the eukaryotic cell. Domains were introduced by Woese, Kandler, and Wheelis to denote that these primary lines of descent constitute higher entities than the traditional eukaryotic kingdoms. The most significant epigenetic differences among members of Archaea and Bacteria are the compositions of the cell wall and fatty acid and the modification pattern of tRNA.

Figure 1 schematically depicts the tripartition of the domain Archaea that guided the description of three kingdoms, the Euryarchaeota, the Crenarchaeota, and the Korarchaeota, for some uncultured organisms. No kingdoms have been described for the rich phylogenetic structure of the domain Bacteria, outlined in **Figure 2**, because of the significantly large number of organisms and lineages involved, which are not always well separated from each other. The order at which these lineages evolved is of low statistical significance but the phylogenetic composition of organisms within these lineages can be recovered by analyses of other genes, such as those coding for 23S rRNA, 5S rRNA, ribosomal proteins, ATPase, elongation factors, and heat shock protein HSP70. In some lineages certain characteristics are indeed of phylogenetic significance, such as morphology and/or ultrastructural features (*Thermotogales*, *Planctomycetales*, *Verrucomicrobiales*, *Spirochaetales*, and *Myxobacterales*), chemotaxonomic properties such as cell wall composition (*Thermotogales/Deinococcus*, *clostridia*, and *Actinobacteria*) or lack thereof (*Planctomycetales*), and physiology, i.e., the composition of the photosynthetic apparatus (*Chloroflexus Chlorobiales*, and cyanobacteria). Most lineages, however, have a wide variation of morphological, chemical, ultrastructural, and biochemical diversity, some traits of which may have been acquired in the course of their evolution by horizontal gene transfer, whereas others may have evolved as a response to occupying new environmental niches (e.g., autotrophic and chemolithotrophic forms). Traits formerly believed to be of monophyletic origin—and hence of taxonomic value—lost their significance in classification when their polyphyletic origin was demonstrated or when these properties were found to be of little genomic stability. In general, this is true for morphology, spore formation, the relationship to oxygen, the presence of a photosynthetic apparatus, gliding motility, and many other characters. In modern classification, these properties are no longer used as the sole basis for the description of higher taxa, such as families, orders, and classes; today, the rationale for a higher taxon is primarily the distinct phylogenetic grouping of its members, whereas their phenotypic description may be rather broad.

A good example of the inability of phenotypic properties to serve as phylogenetic markers is provided by members of the class *Proteobacteria*, which includes the majority of Gram-negative bacteria. This class is highly diverse with respect to

Figure 1 Schematic illustration of the main lines of 16S rDNA sequences showing the tripartition of the domains Bacteria, Archaea, and Eucarya. The circle indicates the approximate position of the root of the tree, making the domains Archaea and Eucarya phylogenetic neighbors. The scale bar indicates 10 estimated changes per nucleotide position.

physiological and morphological properties. Morphological diversity ranges from simple spherical forms to the highly complex fruiting bodies of myxobacteria. Physiologies include chemolithoautotrophy, photosynthesis, fermentation, anaerobic respiration, and nitrogen fixation. To reliably affiliate a new isolate to a described genus by these properties is improbable; the chance of doing so is increased by the presence of unique biochemical properties, such as nitrate or ammonium oxidation (*Nitrobacter* in the α subclass and *Nitrosomonas* and relatives predominantly in the β subclass, respectively) and sulfate reduction (*Desulfovibrio* and relatives; δ subclass). Sulfur and sulfate oxidation as well as anaerobic photosynthesis are poor phylogenetic markers because members of *Thiobacillus* are found in the α , β , and γ subclasses and the sulfurless photosynthetic organisms occupy different sublines of descent within the α and β subclasses.

As a consequence of the recognized discrepancies between the phylogeny of prokaryotic taxa and their previous taxonomic treatment, the recent phylogeny-oriented classification system of genera and higher taxa was developed to primarily match the 16S rDNA data. Newer textbooks have adopted the modern approach, in which, by providing the phylogenetic framework, the origin and evolution of certain phenotypic traits may be better understood than expressed by traditional superficial lumping.

The Diversity of Symbiotic Prokaryotes

Endosymbiotic associations, recognized more than a century ago, initially concentrated mainly on the elucidation of the origin of chloroplasts. Later, the importance of eukaryote-prokaryote relationships was recognized for associations between plants and nitrogen-fixing bacteria, e.g., legumes and *Rhizobium* species, monocots and *Azospirillum* species, *Casuarina* sp. and *Frankia* sp., ferns and *Anabena* sp., and the prokaryotic origin of plant mitochondria. However, most endosymbiotic relationships between microorganisms and their eukaryotic hosts were mainly descriptive and the taxonomic affiliation of the vast majority of uncultured microorganisms remained virtually unknown. In contrast, microbial partners participating in nonobligate symbiotic relationships were identified long before the molecular era; there are numerous associations for the ectosymbiotic microbiota of the rumen, intestine, gut, and skin.

Identification of Symbionts

Most endosymbiotic bacteria are defined as "as yet uncultured" organisms, many of which do not exist as a pure culture within the host tissue. Hence, genes coding for rRNA

Figure 2 Relative order of the main lines of descent within the domain Bacteria based on 16S rDNA sequences. The horizontal portion of triangles indicates the phylogenetic depth of that lineage, whereas the size of triangles is not indicative of species numbers. Lineages from which symbionts evolved are indicated by open arrowheads. Lineages which encompass sequences of as yet uncultured free-living bacteria are indicated by solid arrowheads. The scale bar indicates 10 estimated changes per nucleotide position.

cannot be isolated selectively but must be identified within clone libraries consisting of PCR-amplified rDNA using prokaryote-specific PCR primers and total DNA extracted from the plant, animal, or even the prokaryotic cell. If the host contains a single symbiotic partner only, the clone library will consist exclusively of the one unique rDNA insert; if the association is more complex, the clone library will contain phylogenetically different inserts. Authentication of the symbiont and verification of the location of the putative endosymbiont within the host tissue is performed by fluorescence *in situ* hybridization techniques as elegantly developed by Stahl, Amann, and coworkers. In most cases the 16S rDNA sequence will provide sufficient unique nucleotide stretches to allow generation of symbiont-specific oligonucleotide probes.

Not until 1982 was *Prochloron didemni*, the endosymbiont of the ascidian *Lissoclinum patellum*, identified by molecular techniques. Ten years later, a wealth of information was available on the molecular phylogeny of symbionts and endosymbionts from a broad spectrum of eukaryotic hosts, ranging from protozoa to vertebrates. The availability of a large database, consisting of thousands of 16S rDNA sequences of free-living prokaryotic species, facilitates the search for the phylogenetic affiliation of the more than 500 16S rDNA sequences available for host-associated bacteria. Fundamental questions about the identity of the prokaryotic partner, the evolution of symbiotic relationships, and the mechanisms of symbiont transmission can now be addressed.

The Evolutionary Origin of Symbionts

Most endosymbionts investigated to date originate from ancestors within the domain Bacteria, in which they are found in a few main lines of descent (open arrowheads in Figure 2). The ability to thrive in certain anaerobic protozoa of the genera *Metopus*, *Plagiopyla*, and *Trimyema* appears to be widespread among methanogenic Archaea (kingdom Euryarchaeota). No endosymbionts have been described to share a common ancestry with those prokaryotes which define the most deeply branching lineages, such as the Crenarchaeota, domain Archaea, and *Aquificales*, *Thermotogales*, and other branches comprising thermophilic and phototrophic organisms of the domain Bacteria. Because symbionts and non-symbionts share more than 80% 16S rDNA sequence similarity it can be concluded that the invasion of the eukaryotic host by prokaryotic cells must have occurred less than 2 Gy ago. Figure 3 shows recent evolutionary events by plotting geological time against 16S rDNA similarity values determined for the origin of organisms defined by key physiological types (i.e., oxygen-generating photosynthesis by cyanobacteria, fermentative metabolism in facultative anaerobic bacteria, and origin of respiration chain in aerobic bacteria). Thus, as derived from 16S rDNA similarity values, the origin of endosymbionts correlates with the origin of the eukaryotic cell and endosymbiosis has occurred repeatedly in (perhaps all) eukaryotic lineage.

In order to study the history of symbiotic associations, the phylogenetic trees of hosts and their symbionts should be compared. Few data are available, with the most convincing study being that on the endosymbionts of aphids. The topology of the symbiont *Buchnera aphidicola* tree is completely concordant with host phylogeny based on morphology. The fossil and biogeographic time points for the aphid phylogeny have been used by Wilson and Bauman to calibrate the 16S rDNA of the closely related endosymbionts (>8% similarity). The value of 1% fixed substitutions per 25–50 million years determined for the symbionts of aphids is similar to the value of 1% per 50 million years determined on the basis of a broader range of nonobligate symbiotic relationships (e.g., *Rhizobium*/legumes, *Photobacterium*/fish,

Figure 3 Correlation plot of geological time (as deduced from the fossil record and oxygen content) and 16S rDNA similarity values. Only the past 2 billion years are shown. The origin of aerobic bacteria and symbiotic bacteria correlates with the increased content of oxygen in the atmosphere and the eukaryotic cell, respectively.

and enterobacteria/mammals) and to the value of 1% per 60 million years for the past 500 million years (Figure 3).

The host advantage of the association has been unraveled in a few cases, such as the removal of hydrogen produced from hydrogenosomes of ciliates by archaeal methanogenic endosymbionts, provision of nutritional carbon to the host bivalves by sulfur-oxidizing gill symbionts, or essential amino acids to aphids by their endosymbionts. Application of the PCR techniques has allowed the elucidation of the transmission route of symbionts in ovaries, testis, and gill tissue of tropical lunicid bivalves and deep sea bivalves.

Phylogenetic Affiliation of Endosymbionts

The majority of endosymbionts cluster phylogenetically most closely with Gram-negative free-living bacteria. It can therefore be deduced that Gram-negative bacteria are the most successful candidates for forming symbiosis, including obligate endosymbiotic associations. A few nonproteobacterial symbioses have been described, such as those found between wood-eating cockroaches and termites and spirochetes and Gram-positive host-associated bacteria, such as the micro-parasite *Pasteuria penetrans* (in root-knot nematodes), *Epulopiscium* (a fish symbiont), and *Frankia* (nitrogen fixing on *Casuarina* and relatives). The association between *Sphingobacterium comitans*, a member of the *Bacteroides*/*Flavobacterium* phylum, and the myxobacterium *Chondromyces crocatus* is an example of a prokaryote–prokaryote symbiosis. Endosymbionts of Archaea are members of the kingdom Euryarchaeota and they are, in contrast to those of Bacteria, organisms containing a Gram-positive cell wall. These anaerobic symbionts, originating from ancestors of the families *Methanosarcinaceae*, *Methanomicrobiaceae*, and *Methanocorpusculaceae*, have been identified in several genera of termites and protozoa. The basis of the symbiotic interaction appears to be hydrogen transfer from host to endosymbiont, which can use the gas for methanogenesis.

Symbionts of the Proteobacteria

Proteobacteria embrace organisms known to have close associations with eukaryotic hosts as pathogens, parthenogenesis bacteria, incompatibility bacteria, symbionts, and organelles (such as the mitochondria of plants which evolved from α proteobacterial ancestors). Endosymbionts and nonobligatory associates of the same host may belong to different phylogenetic groups, indicating that the same host is susceptible to more than a single invasion process and that not all symbiotic relationships result in obligate endosymbiosis.

Symbionts of the α Proteobacteria

The α subclass of Proteobacteria contains a wide spectrum of organisms that are closely associated with eukaryotic cells. Prime examples are members of the nitrogen-fixing genera *Rhizobium*, *Sinorhizobium*, *Bradyrhizobium*, *Mesorhizobium*, and *Azorhizobium*. Pathogens include *Afpia*, *Brucella*, *Bartonella*, *Rickettsia*, *Ehrlichia*, *Orientia*, and *Anaplasma*. A highly related cluster of host-associated organisms, including symbionts of insects, cytoplasmatically inherited bacteria such as the parthenogenesis bacteria (PB), and the cytoplasmatic

incompatibility bacteria (CIB) is related to *Wolbachia pipientis*. Other members of this group are the PB and CIB of *Culex* and *Drosophila*. Because of the degree of 16S rDNA similarity among cultured strains, these symbionts must be considered members of the same species. These relationships demonstrate that the common ancestor of *Wolbachia* and relatives invaded a broad spectrum of insect hosts which, as shown by the high values of up to 99% 16S rDNA similarity, must have occurred recently in evolution.

Symbionts of the β Proteobacteria

Members of the β subclass of Proteobacteria encompass a wide range of mainly pathogenic plant- and animal-associated bacteria, such as members of *Burkholderia*, *Azoarcus*, *Ralstonia*, *Bordetella*, *Kingella*, *Eikenella*, and *Neisseria*. Also included in this subclass is the kinetoplast of *Crithidia*. The diversity of endosymbionts, however, is rare and restricted to the endosymbionts of the mealy bugs, which are moderately related members of the genera *Ralstonia* and *Burkholderia*.

Symbionts of the γ Proteobacteria

By far the higher number of endosymbionts of insects and vertebrates are members of the γ subclass of Proteobacteria. In addition, this taxon contains a wide spectrum of animal and human pathogens and nonobligate symbionts such as members of *Enterobacteriaceae*, *Legionellaceae*, *Pasteurellaceae*, *Vibrionaceae*, *Pseudomonas* (sensu stricto), and *Acinetobacter*. Many endosymbionts cluster according to the phylogenetic rank of their hosts, which may be indicative of coevolution events: (i) The primary endosymbionts of giant ants, aphids, tse-tse, and the sweet potato white fly form a phylogenetically coherent cluster within the radiation of enterobacteria; (ii) the symbionts of fish with light organs, such as the deep-sea anglerfish and the flashlight fish, cluster with different members of *Vibrio*; (iii) two moderately related subclusters consist of the gill symbionts of bivalves. These organisms are remotely related to methylotrophic bacteria. The latter symbionts are sulfuroxidizing organisms which provide their hosts with nutritional carbon. Nitrogen-fixing symbiosis is not restricted to plants but the gland of an invertebrate shipworm contains large numbers of γ proteobacteria which possess the ability to digest cellulose and fix nitrogen.

The Diversity of the Uncultured Free-Living Organisms

For more than a century, assessment of prokaryotic species has been evaluated by the culturing approach. The number of different growth media is unknown, but all aimed to recover the largest possible diversity of organisms. However, it is not the enrichment and isolation but rather the lack of cheap and reliable molecular identification methods that still slow microbiologists in their attempts to classify strains to the species level and to describe new prokaryotic species. The number of novel strains that has been eliminated during the isolation process, or which were only included in a biased search for specific properties before they disappeared in non-public resource collections, cannot be counted. It is unknown how many strains have been investigated in parallel. Although this problem may one day be overcome by more facilitated

species definitions and the availability of a global network of biological information, microbiologists are currently confronted with the problem that there is a remarkable difference in the number and morphology of organisms in natural samples with enrichment cultures and isolated colonies. Staley and Konopka introduced the phrase "great plate anomaly" to indicate that only a small fraction of prokaryotic species observed under the microscope will grow under artificial laboratory conditions.

The Vast Majority of Prokaryotic Species Have Not Been Cultured

Pace and colleagues first suggested that rRNA sequences could be used to characterize natural communities without the need to culture. The delay in publishing the first studies by the research groups of Giovannoni and Ward was largely due to the need to develop robust and simple technologies whereby 16S rRNA sequences could be recovered from complex mixtures of environmental nucleic acids and then individually sequenced. Since then, there have been numerous 16S rRNA- and 16S rDNA-based studies in which sequences were analyzed to explore microbial diversity in different environments. Most of these studies differ in details of methodologies, such as isolation of nucleic acids, PCR amplification conditions, and source of cloning vectors and ligation enzymes, but in one aspect the outcome of all of these studies was similar: The vast majority of the more than 1200 environmental partial 16S rDNA sequences, deposited in public databases, were not identical with and often not even similar to the homologous sequences of described species accessible in the extensive databases of cultured bacteria (Figure 2, solid arrowheads). Also, the sequences were rarely identical to sequences obtained from strains that were isolated in parallel to the molecular work from the same environment (Figure 4). As judged from the low degree of sequence similarity, one could even conclude that many sequences are indicative of the presence of higher taxa. This finding reinforced the previously mentioned idea that the vast majority of species have not yet been isolated.

Additional molecular techniques have been developed for understanding the composition of microbial communities that reach beyond the mere assessment of phylogenetic relationships of clones and strains. Among others, methods comprise (i) the application of gradient electrophoresis of PCR-amplified 16S rDNA sequences to facilitate recognition of changes of populations in time and space, (ii) the development of biological probes to detect the presence of genes encoding metabolic enzymes or to identify bacterial species directly in an environmental sample, (iii) the development of biosensors to determined microprofiles of inorganic compounds, (iv) flow cytometry and cell sorting to enumerate and separate groups of organisms according to size and taxon specificity, (v) subtractive hybridization to facilitate comparative analysis of environmental samples, and (vi) extension of the database to include genes other than 16S rDNA (e.g., *nif* genes).

The environments discussed in the following sections were selected because they provide the largest database of

Figure 4 Distribution of 16S rDNA clone sequences, representing uncultured bacteria, within the radiation of 16S rDNA sequences of some cultured bacteria. Origin of clone sequences: MC, Australian soil; PAD, Japanese paddy field; FIE, Japanese soy bean field; NH, north Pacific Ocean. The scale bar indicates 10 estimated changes per nucleotide position.

phylogenetic information on uncultured organisms. Many other environments have been investigated, but the overall picture of prokaryotic diversity is less focused; these include, fresh water, paddy fields, marsh oil, marine plants, bioremediation sites, bioleach reactors, or the multistructured associations between prokaryotes and eukaryotic cells.

The Marine Environment

The Uncultured Archaea

The use of archaeal-specific 16S rDNA PCR primers and subsequent analysis of clone libraries from DNA of oxygenated coastal surface waters and oligotrophic open-ocean samples by the groups of DeLong and Fuhrman revealed the widespread occurrence of two types of archaeal diversity. Analyses of different marine sites, including surface and subsurface waters of the Pacific, Atlantic, Antarctic coastal waters, offshore slope regions, and a deep-sea marine holothurian, have subsequently confirmed the affiliation of archaeal sequences to these two groups. Clone sequences of the first group contained 16S rDNA genes of Crenarchaeota organisms found at depths > 100 to 4800 m, whereas others were found at different

marine sites at more shallow depths. Organisms from which sequences originated constitute a significant component of approximately 5–14% of the marine picoplankton assemblages and were novel and closely related to the archaean “Crenarchaeum symbiosum,” a symbiont of the sponge *Axinella mexicana*. At a lower level of relatedness these sequences form a separate branch at the basis of the kingdom *Crenarchaeota*, where they show some distant relatedness to a group of sequences isolated from sediment organisms of the Obsidian Pool, Yellowstone.

A few sequences have been described to belong to the second sequence group originating from Euryarchaeota and are distantly related to the terrestrial species *Thermoplasma acidophilum*. Except for a holothurian archaeal sequence, they have been retrieved from the same environment from which the crenarchaeotal sequences were obtained, but mostly at lower depth (0–100 m). The high sequence similarity of members of this group from geographically separate sites contrasts the finding by Munson and colleagues, who demonstrated the high degree of phylogenetic diversity between archaeal sequences retrieved from 16S rDNA clone libraries generated from material sampled in marsh sediment samples and adjacent vegetative marshland in the United Kingdom. In this study, clone sequences formed about 15 different phylogenetic groups, each of which was highly to distantly related to cultivated Euryarchaeota species.

The origin of marine archaea is unclear because no representative has been cultured. One may argue that these prokaryotes originate from dormant stages of released commensals or symbionts of marine invertebrates. This view, however, is contradictory to the high cell number of living organisms of this group—up to 14% of the total community. Disturbed deep-sea sediments, which have not been investigated, may be another possible source for these organisms. In contrast, euryarchaeal clone sequences retrieved from surface water material may be of coastal and even terrestrial origin, considering that there is a specific relationship of these sequences to some of the DNA retrieved from coastal salt marsh.

The Uncultured Bacteria

Phylogenetic analysis of rDNA from phytoplankton of the Sargasso Sea by Giovannoni, Britschgi, and coworkers revealed that the majority of the mostly eubacterial sequences were novel to systematists. Some clones represented oxygenic phototrophs and could be assigned to the *Synechococcus* group of the *Cyanobacteriales*. Groups of related sequences of mainly the α and γ Proteobacteria were identified and defined as SAR (Sargasso) groups, showing distant relatedness to cultured bacteria of *Shewanella*, *Vibrio*, and *Oceanospirillum*. Analysis of the phytoplankton from the north Pacific near Hawaii by Schmidt and colleagues led to the unexpected result that the population was very similar to that of the Atlantic Ocean. Some sequences were similar to those of common cultured marine organisms (e.g., *Vibrio*, *Pseudoalteromonas*, and *Chromatium*), whereas others represented novel lineages which were distantly related to the *Fibrobacter* group and *Chlorobium*.

Following studies extended the range of sampling sites in the Atlantic and Pacific Oceans, the Antarctic Sea, and the Mediterranean Sea. Basically, the findings of the first studies were confirmed in that many of the new sequences were highly

related, although not identical, to those defined earlier, irrespective of the location. The ecological role of the hitherto undescribed organisms remains unresolved, although their general physiological capacity is probably similar to that of described species because α Proteobacteria encompass mainly lithotrophic and oligocarbophilic organisms, whereas γ Proteobacteria and cytophages exhibit strong hydrolyzing and degrading capacities. The few sequences of Gram-positive bacteria are probably of terrestrial origin because they are mainly found in coastal regions and in sediments which must be regarded as a deposit mainly for endospore-forming organisms.

Hot Spring Environments

Research in hot spring environments has been stimulated by the discovery of *Thermus aquaticus* as a species of high biotechnological value. The community of mats especially provided an excellent comparison of microbial composition as assessed by selective culture techniques introduced by Brock and Castenholz. Results of the sequence investigations by Ward, Weller, and colleagues clearly demonstrated that even such a rather closed system inhabits a phylogenetically diverse community. Consistent with the findings in the marine environment, none of the recovered sequences closely resembled sequences from cultured taxa isolated from similar environments. Sequences of cultured organisms believed to constitute a major component of the mat community, such as *Synechococcus lividus* or *Chloroflexus aurantiacus*, were not recovered. Analysis of prokaryotic DNA from hot springs located in Yellowstone National Park by Pace and coworkers revealed an unexpectedly large number of distinct bacterial sequences, indicative of novel main lines of descent. Archaeal sequences were determined to be specifically related to sequences from the Crenarchaeota. A few sequences showed high similarities with 16S rRNA sequences of cultivated Archaea, (e.g., *Desulfurococcus mobilis*, *Pyrobaculum islandicum*, and *Thermofilum pendens*) but were not identical to any. The archaeal sequences from the hot spring environment were not closely related to the novel archaeal sequences retrieved from the marine environment, which appear to possess a similar position intermediate to the Crenarchaeota. Results of these studies indicated that the domain Archaea possesses a third line of descent, the kingdom Korarchaeota, suggesting that not only the phylogenetic but also the physiological diversity of the Archaea are significantly larger than reflected by the few cultured representatives.

Soil Environment

In contrast to the early extensive work on different marine sites and hot springs, determination of microbial biodiversity in soil was delayed until appropriate methods were developed that circumvented methodological difficulties such as the isolation of PCR-able DNA from humic acid-containing soil and semiquantitative cell recovery. Despite these shortcomings studies by Liesack and Triplett clearly demonstrated that soil samples from the Southern and Northern Hemispheres contain a rich and varied bacterial flora, including nonthermophilic archaeal members from the kingdom Crenarchaeota.

The first soil sample investigated by sequencing and probing 16S rRNA genes was located in a subtropical, moderately acidophilic, and forested environment in Queensland, Australia. Unexpectedly, only a few sequences were obtained from commonly isolated soil organisms, such as *Streptomyces*, although members of this genus were cultured in large numbers from the same soil sample. The reasons for the low representation of Gram-positive bacteria in libraries generated with universal 16S rDNA primers are not known, but this may be explained by the cell wall structure of resting and dormant cells which fail to disintegrate under mild enzymatic lysis. By using actinomycete-specific primers, Embley and colleagues were indeed able to demonstrate the presence of a rich diversity of these taxa in soil. Alternatively, Gram-positive bacteria may be a minor (numerically) component of the soil flora, with selective isolation exaggerating their numbers. Some Australian soil sequences were closely related to those of nitrogen-fixing species of the α Proteobacteria, but the majority of clone sequences represented novel groups that were only remotely related to known taxa, e.g., *Planctomycetales*, *Actinobacteria*, *Verrucomicrobium*, *Acidiphilium*, and *Thiobacillus acidiphilium*.

Several actinobacterial clone sequences, retrieved from rDNA of different soil types and different geographical locations, formed two clusters grouping remotely with members of *Rubrobacter*, *Acidicrobium*, and *Atopobium*. In addition to their presence in Australian forested soil, their occurrence was verified in a hot spring (Australia), geothermally heated soil (New Zealand), paddy fields and soybean fields (Japan), cultivated soil (Mexico), peat bog and garden soil (Germany), grassland soil (The Netherlands), and forest soil (Finland) (Figure 4). These sequences formed fractions of 1–23% of the respective clone libraries and one of these organisms constituted about 6% of the metabolically active part of a Dutch grassland soil community as shown by ribosomal RNA analysis. It can be deduced that these uncultured organisms are distributed worldwide and play a physiologically important role in the soil ecology.

Conclusions

Despite tremendous progress in the elucidation of prokaryotic diversity, many pitfalls have been identified which influence the composition of sequences in a clone library and hence these data can be used neither to quantify nor to qualify the composition of communities. Any estimation of the relation of cultured and as yet noncultured organisms is nothing more than a guess and not supported by scientific data. Most environmental analyses have revealed a heterogeneous mixture of deep and shallow branching lineages, very few of which have shown close relationships to cultured taxa. Many lineages are very closely related to each other, some of this diversity is due to microheterogeneity at the level of *rrn* operons within a single cell, whereas others may represent true strain diversity.

Although the contribution of rDNA and rRNA to microbial ecology must be considered significant, one molecule alone cannot nearly cover all facets of microbial ecology. Not only must the function of an ecosystem be deduced from analyses of genes expressed through rRNA, mRNA, and proteins, and

not only should the network of broad physiological interactions be verified by *in vitro* reconstitution of isolates but also all these strategies must include data on thorough physical and chemical analysis of the natural sample. Because ecological interactions are performed by strains and not by species, the 16S rDNA is not the appropriate tool to unravel the diversity of this high phylogenetic level. Strain diversity may thus be one or more magnitudes higher than mirrored by the analysis of such an evolutionary conserved gene. Ecological niches must be defined and the difficulty in doing so is increased with the complexity of the sample. Soil samples, for example, are homogenized in that during the isolation of DNA many individual microniches with their individual populations are destroyed. In order to understand ecological interactions, population sizes must be known, strain richness and strain abundance must be assessed, the biochemical diversity of strains must be recognized by applying functional probes for the detection of the expression of specific genes, and physical probes must be applied for the assessment of the chemical and physical conditions of the environment. Modern environmental studies must maintain the isolation component because biotechnological exploitation of cosmid libraries is as desirable as the increase in knowledge of the evolution, phylogeny, and ecology of pure cultures.

Glossary

Alleles Alternative forms of a gene. For example, the mutants *putA601* and *putA736* each have a different mutation in the *putA* gene.

Ames test A genetic test for the identification of carcinogens based on their mutagenic activity initially developed by Bruce Ames. The test relies on the ability of a chemical or physical agent to promote the reversion of different classes of mutations that cause histidine auxotrophy.

Auxotroph A mutant that will only grow when a particular nutritional requirement (e.g., amino acid, nucleotide, or vitamin) is provided.

Genotype A specific description of the genetic constitution of an organism. The genotype is defined by the allelic form of each gene in an organism, but for simplicity usually only differences from the wild type are described.

Mutagen A chemical or physical agent that increases the frequency of mutation, usually by directly damaging the DNA.

Mutation Any heritable alteration in the base sequence of the genetic material.

Phenotype The appearance or other observable characteristics of an organism. The phenotype expressed by an organism depends on the particular forms of its genes (e.g., its wild-type or mutant alleles) and the environmental conditions.

Suppression The restoration (or partial restoration) of a wild-type phenotype by a second mutation. There are many different potential mechanisms of suppression.

Transposon A genetic element which, in addition to encoding the proteins required for its own transposition, confers one or more new observable phenotypes (often resistance to one or more specific drugs) on the host cell.

Mutations and Mutagenesis

A powerful feature of bacterial genetics is the ability to examine very large populations of cells (typically $>10^{10}$) for extremely rare types of mutants. Mutations can arise in a variety of ways, including rare errors in DNA synthesis or DNA repair. The probability that a spontaneous mutation will affect a particular base pair varies from about 10^{-7} to 10^{-11} per generation. Thus, in a population of bacteria, about 1 in 10^9 cells may have a mutation in a particular gene. The frequency of mutations can be increased by certain chemical or physical agents called mutagens. Mutagens may act by increasing the frequency of errors during DNA synthesis or repair or by directly altering the DNA. Direct exposure of bacteria to a mutagen may increase the frequency of mutations in a population of cells from 10^3 - to 10^6 -fold. Thorough genetic analysis requires many types of mutations, but each particular method of mutagenesis yields different subsets of mutations.

Effects of Mutations

Bacterial mutants are typically described by comparison to a standard, well-characterized, reference strain called the 'wild-type' strain. Bacterial mutants have often lost some growth property (e.g., failure to utilize a particular carbon or nitrogen source or failure to grow without a particular nutrient), or acquisition of some new growth property (e.g., ability to grow in the presence of some toxic substance). Genes can be divided

into two categories based on the phenotypes of the corresponding mutants: nonessential gene products are only required under specific growth conditions, whereas essential gene products are required under all conditions. The genes of lactose catabolism are nonessential because they are only required for growth on medium with lactose as the sole carbon source. In contrast, the genes encoding RNA polymerase are essential because they are required for growth on all media. Null mutations in a nonessential gene will prevent growth on a medium that requires that gene product but such mutants will still grow on other media. In contrast, null mutations in an essential gene are lethal. Consequently, such mutants cannot be recovered from haploid bacteria. Nevertheless, it is possible to isolate more subtle mutations in essential genes. For example, it is possible to isolate mutations that alter a subunit of RNA polymerase that make the organism resistant to the antibiotic rifampicin. It is also possible to isolate mutations where some phenotype is observed under certain 'nonpermissive' conditions but not under other 'permissive' conditions (Table 1).

Because not all mutations have an observable effect, it is important to distinguish the genotype from the resulting phenotype. In bacterial genetic nomenclature a three-letter mnemonic refers to a pathway or discrete cluster of physiologically connected systems. A fourth, capitalized letter represents a particular gene of that set. The genotype is written in lower case letters and italicized (e.g., *purB*), with a plus superscript indicating the wild-type genotype. (The *purB* gene encodes one of the enzymes required for purine biosynthesis.)

The phenotype is indicated by the same mnemonic but the first letter is upper case and it not italicized (e.g., PurB), with a plus superscript indicating the functional phenotype and a minus indicating a mutant phenotype. The genotype of a cell is usually inferred from its phenotype but may also be determined indirectly by recombination experiments or directly by DNA sequencing

Isolation and Characterization of Bacterial Mutants

Genetic analysis begins with the isolation of mutants that affect some property of the bacteria. Since mutations are very rare, mutants must be isolated from large populations of wild-type cells. Thus, some tactic is needed to find the rare mutants within a vast excess of parental bacteria. It is possible to identify mutations by physical methods such as DNA sequencing, but because mutations are so rare this approach is not usually practical. Instead, mutants are usually identified on the basis of an observable effect on the physiology of the cell. Detection of mutants requires a genetic selection or screen (Table 2).

A selection is an experimental arrangement that allows specific mutants, but not the parental cells, to grow. Genetic selections are very powerful because they allow the direct isolation of rare mutations from a very large population of cells. Some useful selections include resistance to antibiotics, resistance to phage, or the ability to grow on a medium where the parental cells cannot grow. For example, selection for streptomycin-resistant (Str^R) mutants simply requires exposing a large number of bacteria to medium containing

streptomycin-sensitive bacteria are killed by the antibiotic and resistant mutants grow.

The ability to grow bacteria on solid media (i.e., agar plates) under conditions where each cell forms a single colony allows one to carry out screens that distinguish a particular mutant from other bacteria in the population. If the mutation is relatively common and no direct selection for the mutant phenotype is available, it is possible to screen for mutants on media where both the mutant and parental cells grow, but where the mutant has a readily scorable phenotype. For example, mutants of *Escherichia coli* unable to degrade lactose can be identified on indicator media, such as MacConkey-lactose color indicator plates. MacConkey-lactose plates contain a carbon source that can be used by Lac^+ cells, and peptides that can be used as a carbon source by both Lac^+ and Lac^- cells. Both the Lac^- mutant and the Lac^+ parental cells can therefore grow on MacConkey-lactose medium. However, MacConkey-lactose medium also contains a pH indicator that is colorless at high pH but red when the pH decreases owing to fermentation of the lactose, so Lac^+ bacteria form red colonies and Lac^- bacteria form white colonies. Hence, it is possible visually to screen for Lac^- mutants by looking for rare white colonies on MacConkey-lactose plates.

Screens for other types of mutants are not this simple. For example, when mutations disrupt a biosynthetic pathway, the bacteria cannot grow unless the endproduct of the pathway is provided in the medium (permissive medium). It is not possible to isolate such 'auxotrophic mutants' by directly screening for growth on media lacking the endproduct because the desired mutants will not grow (nonpermissive medium). However, auxotrophs are readily identified by replica plating. The bacteria are grown on permissive medium at a density of several hundred colonies per plate. Each of these 'master plates' is then replicated onto two other plates, containing either the permissive medium or the nonpermissive medium. The bacteria are transferred to an identical position on each of the replica plates. Once colonies are identified that grow only on the permissive medium, the mutants can be isolated from the master plate (Figure 1).

The difference between a selection and a screen has important practical consequences. Compare the selection for a Str^R mutant with a screen for a His^- mutant. Isolation of a Str^R colony is a direct selection because as many as 10^{10} cells can be

Table 1 Some types of conditional mutations used in bacterial genetics

Conditional mutation	Permissive conditions	Nonpermissive conditions
Temperature sensitive (Ts)	30 °C	42 °C
Cold sensitive (Cs)	42 °C	30 °C
Osmoremedial	High osmotic strength	Low osmotic strength
Suppressor sensitive	Host with suppressor mutation	Host lacking suppressor mutation

Table 2 Isolation of bacterial mutants

Approach	Features	Sensitivity	Examples
Selection	Condition where only mutant cells can grow	$> 10^{-9}$	Resistance to antibiotics or toxic substrate analogs; resistance to phage
Screen	Condition where both mutants and parental cells can grow, but the mutants have a phenotype that is distinguishable from the parent	10^{-2} – 10^{-3}	Indicator medium to identify mutants unable to ferment a carbon source; replica plating to identify auxotrophs
Enrichment	Condition where survival of the mutant is favored over the parental cells; usually employs an antibiotic that selectively kills growing cells or a condition that kills cells able to incorporate a particular substrate; a genetic screen is needed to identify the resulting mutants	10^{-2} per cycle	Penicillin enrichment; D-cycloserine enrichment; radioisotope suicide

Figure 1 Replica plating. This simple technique makes it possible to test many individual mutants for their ability to grow on a variety of different types of media. After pressing the sterile plates to the velvet replica of an original ('master') plate, the newly inoculated plates are incubated to allow the colonies to grow.

spread on a single plate containing streptomycin and only Str^R mutants will form colonies. Thus, Str^R mutants as rare as 1 in 10^{10} can be isolated easily. In contrast, finding an auxotrophic mutant involves screening through a large number of colonies for one that fails to grow in the absence of the required nutrient. To score the growth behavior of individual colonies, only a few hundred colonies can be examined on any given plate. Thus, if 1 in 10^5 cells in the population were a particular auxotrophic mutant, thousands of plates would be needed to find a single mutant. Treating populations of cells with a mutagen may increase the fraction of mutants to 1 in 10^3 , allowing screening for the desired mutant on a reasonable number of replica plates. Nevertheless, random mutagenesis may not increase the mutant fraction sufficiently to screen easily for the desired mutants, and mutagenesis may lead to other, undesirable mutations as well.

Isolating rare mutants is generally achieved by using some sort of enrichment, a method that favors the growth of the desired mutants relative to nonmutant bacteria. Penicillin enrichment is a classical example of this approach. This antibiotic disrupts the synthesis of the bacterial cell wall. Nongrowing bacteria do not engage in cell wall synthesis, so penicillin only kills actively growing bacteria. The differential survival of growing versus nongrowing bacteria can be used to enrich for a desired mutant. For example, penicillin enrichment can be used to isolate a rare auxotrophic mutant from a population of bacteria. If a mixture of wild-type and auxotrophic bacteria are suspended in the nonpermissive medium containing penicillin, the auxotrophic mutants do not grow and thus will survive, whereas 99% of the wild-type bacteria will grow and be killed by the penicillin. When the surviving bacteria are washed free of the penicillin, and resuspended in permissive medium, both the mutant and wild-type bacteria will grow, but the ratio of mutant to wild-type bacteria will be enriched 100-fold. Repeating this procedure multiple times eventually increases the proportion of mutants in the population (Figure 2).

Genetic Exchange

Exchange of DNA between bacteria plays an important role in evolution. Gene transfer in nature can result in the acquisition of antibiotic resistance and new virulence traits. Gene transfer is also a useful tool in the laboratory, allowing genetic mapping and complementation tests, and the construction of bacterial strains with multiple mutations. The three most common methods of gene transfer between bacteria are transformation, conjugation, and transduction (Table 3). A suitable selectable marker is required to identify recipients that have inherited the desired region of donor DNA.

Transformation

The uptake of naked DNA is called transformation. Some species of bacteria are naturally transformable. At some stage during growth they express gene products that facilitate the uptake of exogenous DNA, a condition called 'competence.' The physiological conditions required to induce competence differs for different species of bacteria. However, most natural transformation seems to involve the degradation of one strand of the exogenous DNA during the transfer of the other strand of DNA into the cell. Stable inheritance of the donor DNA requires either that it be replicated (e.g., some plasmids and phage) or that it integrate into the recipient chromosome via homologous recombination.

Many types of bacteria are not naturally transformable but can be induced to take up DNA by treatment with specific chemicals or by electric shock, processes that are mechanistically different from natural transformation. A common method of chemical transformation in *E. coli* uses hypotonic Ca^{2+} shock. To prepare competent bacteria by this method, an early-exponential phase culture of cells is suspended in a cold hypotonic CaCl_2 solution. When DNA is added to these bacteria it forms a calcium–DNA complex that adsorbs to the

cell surface. The bacteria are then briefly warmed (heat shocked), which allows the DNA to enter the cell. In electroporation, cells are exposed to an electric field, so that a voltage potential develops across the membrane, transiently forming small pores that allow entry of exogenous DNA. In contrast to natural transformation and chemical transformation, which

only seem to work in certain bacteria, a wide range of bacteria can be transformed by electroporation.

Conjugation

DNA can also be transferred between bacteria by a process called conjugation. Conjugation occurs via cell–cell contact and the formation of a mating channel. This structure is formed by specific proteins that form a pore between the juxtaposed membranes through which single-stranded DNA and some associated proteins are transferred into the recipient cell. Conjugation requires four events: (1) contact between donor and recipient cells and formation of a mating appendage; (2) nicking of the donor DNA at specific sites; (3) translocation of the nicked strand of donor DNA to the mating bridge and into the recipient cell; and (4) replication of the transferred DNA in the recipient cell. The proteins required for conjugation are usually encoded on specific plasmids or transposons. These conjugal plasmids or transposons can transfer themselves or, if integrated into another region of the genome, any adjacent genomic sequence. Thus, conjugation can result in the transfer of very large DNA fragments – even chromosome length DNA fragments. Furthermore, some conjugal plasmids are quite promiscuous. In addition to transferring DNA into a wide variety of bacteria, some conjugal plasmids can transfer DNA into Archaea and eukaryotes as well (Figure 3).

Transduction

Transduction is the transfer of bacterial DNA from one cell to another by a phage particle. Phage particles that contain bacterial DNA are called transducing particles. There are two types of transduction: generalized and specialized.

Generalized transduction requires an error during the packaging phase of phage maturation, such that random, phage-size fragments of chromosomal DNA get inserted into the phage head in place of phage DNA. Thus, in a lysate of a generalized transducing phage some particles contain DNA obtained from the host bacterium rather than phage DNA. The bacterial DNA fragment can be derived from any part of the bacterial chromosome. When these phage particles adsorb to a recipient, the double-stranded chromosomal DNA is injected. Stable inheritance of the donor DNA requires either

Figure 2 An example of the use of penicillin enrichment to isolate auxotrophic (aux^-) mutants from a population of prototrophic (aux^+) bacterial cells. Each cycle results in about $100 \times$ enrichment of the desired mutants.

Table 3 Common mechanisms of natural gene transfer in bacteria

Transfer mechanism	Vehicle	Properties
Transformation	–	Uptake of naked DNA from environment; recipient cell must be competent
Conjugation	Conjugal plasmid or transposon	Requires cell-to-cell contact; very long fragments of DNA can be transferred to recipient cell
Generalized transduction	Phage	Phage-length fragments of chromosomal DNA transferred to recipient cell; phage head only carries host DNA
Specialized transduction	Lysogenic phage	Short fragments of chromosomal DNA transferred to recipient cell; phage head carries host DNA covalently attached to phage DNA

that it be replicated (e.g., following transfer of plasmids) or that it integrate into the recipient chromosome via homologous recombination. Generalized transducing particles arise during lytic growth of both virulent and lysogenic phages (Figure 4).

Specialized transduction results from the aberrant excision of an integrated lysogenic phage. In contrast to generalized transduction, the phage head packages contain a contiguous molecule having both host and phage DNA. Only regions of the host DNA that flank the prophage are packaged.

By using genetic tricks to force lysogenic phages to integrate at many sites in the genome, it is possible to isolate specialized transducing phage from many different regions of a bacterial genome. Stable inheritance of specialized transducing fragments can occur either by phage-specific processes or by homologous recombination mediated by bacterial recombinases.

Genetic Analysis of Bacterial Mutants

Three of the most important tools for the analysis of bacterial mutations are suppressor analysis, genetic recombination, and complementation. Suppressor analysis facilitates the dissection of the roles of gene products and how they interact with other gene products. Recombination allows the construction of new combinations of genes and the elucidation of the positions of genes on a chromosome relative to other genes. Complementation can reveal how many genes are responsible for a particular phenotype and can distinguish regulatory genes from regulatory sites.

Reversion and Suppressor Analysis

Mutant organisms can regain their wild-type characteristics by means of a mutation that restores function, by a process called reversion. Reversion can either be owing to 'true reversion,' a back mutation that restores the original genotype, or 'suppression,' a second mutation that produced a change that partially or fully compensated for the first mutation. The ability to analyze very large populations of bacteria facilitates the isolation of rare classes of such revertants.

The reversion frequency is a useful criterion for classifying mutants. The reversion frequency can distinguish a single point mutant from a double mutant or a deletion mutant: single point mutants (which can be repaired by a single back mutation) revert at a much higher frequency than double mutants (which require two changes and thus revert very rarely) or deletion mutants (which cannot directly revert). The effect of

Figure 3 Conjugation is a process of DNA transfer via direct contact between a donor cell that carries a conjugal plasmid such as the F-plasmid, and a recipient cell that lacks the conjugal plasmid. A pilus protruding from the surface of the donor cell recognizes the recipient cell and promotes close contact between the two cells, forming a bridge through which DNA is transferred. On cell-cell contact the conjugal plasmid is nicked at a specific site called *oriT* (indicated by the arrowhead), and the DNA is transferred from this site into the recipient cell. After conjugation is complete, both cells have a complete copy of the conjugal plasmid.

Figure 4 Transduction is the process of packaging of a portion of the genome from a donor cell into a virus particle (e.g., a bacteriophage) and the subsequent delivery of the genetic material to a recipient cell. Once in the recipient cell the fragment of donor DNA can recombine with the genome of the recipient yielding a new phenotype (in the case shown, via conversion of the recipient from an arginine auxotroph into an arginine prototroph). The altered recipient cell is called a transductant.

mutagens on the reversion frequency can also be used to distinguish different types of mutations – reversion of frameshift mutations is stimulated by frameshift mutagens, and so on. For most purposes this approach has been superseded by direct DNA sequence analysis; however, the reversion of known bacterial mutations remains an important assay to detect potential human carcinogens (for example, using the Ames test).

Second site mutations that result in suppression can occur within the same gene as the original mutation (intragenic suppression), or within a different gene (intergenic suppression). Intragenic suppressors can provide information about the role of particular amino acids in a protein, protein folding, and interactions between different amino acids within a protein. Intergenic suppressors can occur in a variety of ways, and each provides different insights into the structure or function of the gene products involved. Suppressor mutations often result from 'gain-of-function' mutations that are dominant over the wild-type gene. Thus, characterization of suppressors requires genetic recombination to construct strains with different combinations of mutant alleles, and complementation analysis to determine dominance.

Homologous Recombination

Genetic recombination is the physical breakage, exchange, and rejoining of two DNA molecules. Homologous or general recombination can be mediated by several different pathways in bacteria. Each of these pathways requires the RecA protein to align the DNA molecules between regions of substantial DNA sequence identity. The DNA molecules are broken between random but matching nucleotides, and then the DNA fragments are exchanged and rejoined to form two new combinations of genes. For example, recombination between two DNA molecules with the genotypes a^+b and ab^+ can yield two recombinant DNA molecules with the genotypes a^+b^+ and ab . Owing to the efficiency of gene transfer and the ability to work with large populations of bacteria, recombination analysis can be sufficiently sensitive to detect recombination events between adjacent base pairs.

Recombination can be used not only to construct strains with different genotypes, but can also reveal the relative map location of genes. The probability of recombination between any two adjacent base pairs is very low, but the probability of recombination between base pairs within a homologous DNA sequence is essentially random. Hence, the physical distance between two genes located on the same DNA molecule determines the frequency of recombination between the genes: the probability of recombination is less if the genes are close to each other than if the genes are farther apart (Figure 5).

Genetic mapping exploits the recombination frequency between genes to measure the relative distance between genes. In bacterial genetics, the probability that recombination did not occur between genes is usually determined. If recombination does not occur between two genes, the genes will be coinherited. For two genetic markers on the same DNA molecule, the closer two genetic markers are to each other, the more often they will be coinherited. The frequency that two genes are coinherited is defined as their linkage. Determining the linkage of two genetic markers is called a two-factor cross. It is also possible to determine the relative location of genetic mutations by using three genetic markers (three-factor crosses) or by genetic crosses involving a set of defined deletion mutations (deletion mapping). Although it is possible to determine the relative location of genes by hybridization or DNA sequencing, genetic mapping often provides a simple and

Figure 5 Complementation analysis provides a genetic test for particular functions encoded by different genes. (a) Assume that in a cell substrate W is converted in three enzymatic steps to the endproduct Z, and that each of these enzymatic steps is encoded by a different genes (*a*, *b*, and *c*). (b) If any one of these genes is defective in a haploid bacterial cell, then that cell will be unable to make the endproduct. (c) If two copies of these genes are placed in a single bacterial cell, and if both copies are defective for the same gene, then the cell will be unable to make the endproduct. In this case, we say that the second copy did not complement the original mutation. (d) If the two copies of the genes are defective for different genes, then at least one functional gene is present for each step in the pathway, and the endproduct will be made. If the second copy compensates for the defective function, then we say that the mutation was complemented.

inexpensive way to determine rapidly the location of mutations in bacteria.

Recombination also provides an invaluable tool for constructing strains with multiple mutations. If a mutation involves a directly selectable phenotype, it can be transferred with ease

from a donor to an appropriate recipient strain. If the mutation cannot be directly selected, linkage to an adjacent, selectable marker can be used to move the mutation into a recipient strain. For example, an auxotrophic mutation may be transferred by selecting for coinheritance of a nearby gene.

To determine the genetic or biochemical effects of a mutation, it is necessary to compare a mutant with a strain that only differs by a single mutation. If several mutations are present, it is not obvious which of the mutations is responsible for an observed phenotypic change. Two organisms that differ by only a single mutation are said to be isogenic or to have the same genetic background. The most common way to ensure that two strains are isogenic is to transfer a small region of DNA carrying the mutation into the parental strain by recombination.

Complementation Analysis

A particular phenotype frequently reflects the activity of many genes. To understand any genetic system it is essential to know the number of genes and regulatory elements involved. Since multiple genes that affect the same function may map very close to each other, it is not possible to determine if two mutations are in the same or different genes simply from the recombination frequency. For a variety of reasons, it is also often difficult to prove that two mutations affect the same gene product by DNA sequence analysis. However, this question can be addressed by genetic complementation.

Bacteria are normally haploid, but complementation requires the maintenance of two copies of a particular gene in the same cell. In bacteria this can be done by constructing a partial diploid or 'merodiploid' that carries two copies of the relevant genes. Partial diploids may provide one copy of the gene on the chromosome and a second copy of the gene on a plasmid. For example, the partial diploid *lacZ*/*lacZ*⁺ has both a copy of the *lacZ* gene and second copy with the *lacZ*⁺ gene. If the functional copy of these genes encodes a protein that can diffuse through the cell to perform its function, and the second copy has a loss-of-function mutation, the functional copy of the gene will be dominant over the mutant copy. Thus, even though the *lacZ* gene on the chromosome cannot produce beta-galactosidase, the plasmid-borne *lacZ*⁺ gene makes beta-galactosidase so the cell is phenotypically Lac⁺. The mutant is complemented by the wild-type gene, indicating that the mutation is recessive. In contrast, the partial diploid *lacZ*/*lacZ* cannot make beta-galactosidase so the cell is phenotypically Lac⁻. If two recessive mutants fail to complement, they affect the same gene (Figure 6).

Complementation analysis in bacteria usually follows the grouping of mutations by genetic mapping experiments. This reduces the number of partial diploids that must be constructed because genes that map far from each other are clearly different. In addition, complementation analysis should involve partial diploids with an equal number of copies of each gene. If one of the genes is present in excess (for example, with genes cloned on multicopy plasmids) artifacts can occur which may be very misleading.

Portable Regions of Homology

Although most genes have a specific, defined location in a bacterial genome, the genome is by no means static. Recombination between repeats of homologous DNA sequences can result in the duplication, deletion, or inversion of the

Figure 6 Recombination is the breaking and joining of two homologous DNA molecules. The exchange occurs between two homologous base pairs, generating a join point between the two parental DNA molecules. Because the recombination can occur between any of the base pairs in homologous sequences, the further apart two genes are, the more likely there will be a recombination event between them.

intervening DNA. It is possible to select for insertion of such homologous sequences at strategic positions in the genome. Such 'portable regions of homology' can be generated by transposable elements, which are mobile segments of DNA that move to new locations at low frequency. Alternatively, having specific DNA fragments on a circular DNA molecule (e.g., a plasmid or phage) can permit the targeted insertion of DNA into a particular site on the chromosome. These two types of insertions have a wide variety of genetic uses. A few examples include: construction of insertion mutants with complete loss of function; construction of deletion mutations with defined endpoints; construction of duplication mutations for complementation studies; integration of other genetic elements at particular sites in the genome by homologous recombination; transfer of mutations by selection for an associated genetic marker (e.g., antibiotic resistance); isolation of linked genetic markers with a selectable phenotype; and construction of operon or gene fusions.

Transposable Elements

Transposable elements in bacteria include insertion sequences and transposons. Insertion sequences are short elements (typically less than 5 kb) that only encode functions required for their own transposition. Transposons are typically longer (>5 kb) and encode other gene products (e.g., antibiotic resistance) in addition to the functions required for transposition. The frequency of transposition of these elements is typically low, although the frequency varies over a wide range (10^{-7} – 10^{-2} per generation). Transposition requires both cutting the DNA at each end of the transposon and the target DNA site, joining the ends of the transposon and target DNA molecules, and DNA replication. Transposition can occur by a replicative mechanism (requiring replication of the entire transposon) or nonreplicative mechanism (requiring only replication of short fragments at the end of the insertion site). Both mechanisms are independent of the homologous recombination machinery of the host.

Transposable elements play an important role in bacterial evolution, including the transfer of antibiotic resistance genes between bacteria and promoting chromosome rearrangements. In addition, transposable elements are useful tools in bacterial genetics because they provide selectable markers and portable regions of homology that can be used to facilitate genetic recombination.

Integration of Circular DNA Molecules

In addition to transposons, it is possible to construct small repeats of homologous DNA by integration of a circular DNA molecule with a cloned fragment of chromosomal DNA. This approach is useful for construction of defined duplications for complementation analysis and for construction of insertion mutations on the chromosome. Recombination between the homologous sequences of the resulting duplication can result in allele exchange, moving a mutation from a cloned sequence onto the chromosome DNA.

Summary

A hallmark of bacterial genetics is the ability to analyze very large populations of cells to identify rare genetic events.

Although a wide variety of genetic tricks have been developed for specific purposes in particular bacteria, bacterial genetics relies on a relatively small core of tools for dissection of the structure and function of genes. The essential tools include the isolation of mutations, the ability to transfer genes between bacterial strains, the ability to isolate recombinants, and the ability to do complementation tests. These tools have been finely honed for a select group of model bacteria, including *E. coli*, *Salmonella enterica*, and *Bacillus subtilis*. The concepts developed for these model bacteria are readily applicable to other bacteria as well, although the experimental details typically require adaptation for each particular species of bacteria.

Ecogenomic Sensors

Christopher A Scholin, Monterey Bay Aquarium Research Institute, CA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Autonomous sensor Device that allows for automatic detection of chemical, physical, or biological properties absent human intervention.

Cabled observatory Cable on the seafloor that provides electrical power and high-speed communications between sensors in the ocean and the Internet (*see also* Ocean observatory).

DNA probe array Collection of short, single-stranded, uniquely addressable segments of deoxyribonucleic acid (DNA) attached to a solid surface that are used to detect the presence or expression of specific genes via the principles of nucleic acid hybridization.

Functional gene Recognizable, heritable segment of DNA that encodes for proteins involved with cell metabolism.

Genomics Discipline of genetics that focuses on the study of the complete genetic content of species, often by determining the entire DNA sequence of organisms and expression and function of their genes in relation to various stimuli or metabolic perturbations.

In situ Latin phrase meaning “in position”; here, its use is synonymous with “in water.”

Ocean observatory Collection of airborne and in-water sensors for characterizing oceanic chemical, physical, and biological parameters that may vary over time. Sensors comprising an ocean observatory are mounted on various platforms (e.g., satellite, aircraft, moorings, autonomous underwater vehicles, benthic cable) that typically provide communications capabilities for transmitting sensor outputs and for receiving instructions from a remote location. An assortment of sensors and platforms spread over a distance may also be referred to as a *distributed ocean sensor array*.

Protein probe array As per DNA probe array, only with proteins that serve as sensing elements.

Real-time Instantaneously; without latency. In the ocean sciences, this phrase is often used with respect to the amount of time between sensor function and data transmission.

Remote operations Controlling and communicating with autonomous systems from afar.

History of the Ecogenomic Sensor Concept

Ocean scientists had conceived of ecogenomic sensors many years before the phrase was coined and put into common practice (Scholin, 2010). The origins of that name are closely tied to an image put forth in 2005 by Hunter Hadaway, a graphic artist (**Figure 1**). Prior to that time, the term *ecogenomics* was being used to describe the merger of high-throughput DNA sequencing with environmental science interests. Among the many attempts to capture this idea graphically was a figure promoted by Anna Palmisano, who once combined images of a satellite, a ship, and a DNA microarray to illustrate how genomic approaches for studying marine microbes could be nested within a variety of other ocean-observing capabilities. Virginia Armburst encouraged Hadaway to meld Palmisano's ideas with the notion of an ocean bottom cabled observatory and satellite imagery. From those inputs emerged Hadaway's iconic image carrying with it the term *ecogenomic sensor*. The concept of an autonomous

ocean sensor network had been successfully fused with the burgeoning field of ecogenomics. Those who had been working independently for years at that very interface could at once point to a common image that captured the essence of their collective vision: a field-deployable device that enables the remote detection of targeted organisms, genes, and gene products using molecular probe technologies.

Implicit in **Figure 1** was that a larger ocean observing system provided an environmental context through which the outputs of ecogenomic sensors would be viewed. In keeping with the vanguard cabled-observatory concept proposed at that time, nearly unlimited power and high-bandwidth communications networks would allow ecogenomic sensors to transmit results of analyses instantly and also allow researchers to redirect activity of those devices based on inputs conveyed via the larger, distributed sensor array. Ecogenomic sensors would thus become an extension of ship- and shore-based laboratories, opening a new window for observing biological processes in the sea. It was a grand vision.

Figure 1 Artist's rendition of ecogenomic sensors embedded within an array of airborne and in-water sensors. This image was cast in the broader vision of the US Ocean Observatories Initiative (OOI).

Pieces of that puzzle were in fact in various stages of development in 2005, with some parts operational and others experimental, but the complete system as depicted did not yet exist.

The initial motivation for developing ecogenomic sensors took root many years prior to the release of Hadaway's figure and emerged from much more humble beginnings. The widespread use of molecular biological methods as a means to reveal the diversity, relationships, and functions of marine organisms had been a fixture in the ocean sciences for decades. Traditionally, such investigations often required transporting discrete field samples to a laboratory for subsequent processing and data generation. That requirement stood in sharp contrast to characterizations of many basic chemical, physical, and optical properties of waters (e.g., temperature, salinity, chlorophyll fluorescence) that can be obtained near instantaneously while at sea. The disparity between the effort and time required for molecular analytical analyses versus real-time, bulk ocean characterizations was a long-standing limitation that drove the conceptualization of ecogenomic sensors. Previous engineering developments had made real-time assessments of many fundamental ocean properties possible. By extension, that progression applied equally to inventing new machines that would use molecular biological techniques to conduct measurements *in situ*; initially, it was a relatively modest and unencumbered proposition.

The push to develop ecogenomic sensors stemmed from studies of microorganisms such as viruses, bacterioplankton, phytoplankton, small zooplankton, and larval stages of larger animals. Under many circumstances, there is a need to rapidly

identify and quantify particular species that may be rare and that cannot be distinguished easily. Applications related to water-quality monitoring, aquaculture and detection of invasive species exemplify such situations. DNA probe technology offers one way for enhancing organism detection, but the reliance on returning samples to a laboratory often nullifies many of the advantages that approach provides. Similarly, the idea of assessing the genomic capacity and activity of a community or population of organisms in real-time is desirable, particularly as a means to understand how organisms respond to environmental perturbations over daily, seasonal, annual and interannual time scales. In all cases, an ability to assess organism presence, abundance and activity *in situ*, instantaneously, can enhance decision making opportunities with respect to resource management and field research operations (e.g., Bowler *et al.*, 2009). Most importantly, a remote sensory presence allows for continued observations absent a human presence. It was from that confluence of innovations in genomics and ocean observatories that the first attempts to develop and deploy ecogenomic sensors grew.

Technical Challenges

The application of molecular analytical techniques in the aquatic sciences traditionally relies on laboratory personnel collecting discrete samples and processing them by applying a series of procedures that utilize various pieces of equipment housed in a laboratory. Automating and integrating that sequence of steps – from sample acquisition through

conditioning/fractionation to biochemical analyses – is a major challenge to realizing the ecogenomic sensor vision. Current, accepted laboratory methods that encompass that full sample processing cycle were never constrained by a need for hands-free operation for extended periods of time under ambient field conditions, let alone whilst submerged below the sea surface. Therefore, the development of ecogenomic sensors requires a philosophical departure from traditional wisdom derived from decades of conventional shipboard and laboratory operations.

A primary technical difficulty associated with such sensors is the need to acquire relatively large volumes of native water (often liters (l's) since target organisms may be rare), concentrate various sized particles, and then apply to the material retained a variety of chemical solutions on milli- and micro-fluidic (ml, μ l) scales or lower. For example, using traditional laboratory methods, collection of particulate matter from 1 to 2 l of seawater might typically yield 50–100 μ l of extracted nucleic acid, from which one to several microliters of extract (or less) may be used in a subsequent polymerase chain reaction (PCR) reaction (e.g., *Preston et al.*, 2011 and references therein). In that simple case, automation of the procedure dictates fluid handling capabilities that scale over at least six orders of magnitude. In addition, the procedure demands accessing “live” sample water that may contain a diverse assemblage of organisms and particulate matter, as well as highly refined, sterile and sensitive biochemical reagents. Raw sample water and other reagents must be partitioned and the integrity of each not compromised by cross contamination with others.

Most traditional molecular analytical methods also rely on expendable supplies and chemicals maintained and utilized under strict temperature regimes. Translating this approach to an autonomous machine creates a need for storing sample processing materials and ensuring that they remain stable and in good working order under conditions that are far from that of a shore based laboratory. Any design is further complicated when the details of different detection methodologies and intended uses or deployment locations are brought under scrutiny. Consequently, there is no single, overarching electromechanical design that satisfies the generic definition of an ecogenomic sensor (*Scholin*, 2010).

Those who have worked to automate sample processing for environmental science applications are by no means alone in their quest. Commercial ventures have pursued similar ideas for decades, giving rise to present-day companies that offer highly sophisticated, automated laboratory and field portable instruments (e.g., Cepheid (California, USA), Enigma Diagnostics (Salisbury, UK), Seattle Sensor Systems (Washington, USA)). However, such platforms were primarily designed around specific biomedical diagnostic or bio-threat detection applications, and the input volume of raw sample is extremely limited. Many research laboratories have also worked on developing portable instrument systems, or components thereof, that incorporate nucleic acid, antibody and/or receptor-based assays for use with environmental samples. Like the commercially available products, those systems are not necessarily suited for underwater use and generally require some type of laboratory infrastructure or personnel to effect a complete cycle of sample collection, processing and data transmission (e.g., *Bruckner-Lea et al.*, 2002; *Belgrader et al.*, 2003; *Chandler and Jarrell*, 2004; *Fukuba et al.*, 2004; *Hindson et al.*, 2004, 2005, 2008; *Straub*

et al., 2005; *Casper et al.*, 2007; *Chinowsky et al.*, 2007; *LaGier et al.*, 2007; *Regan et al.*, 2008; *Bahi et al.*, 2011).

In a brief review of optical and molecular analytical ocean instrumentation published in 2007, *Paul et al.* (2007) summarized the progress that had been made in realizing the ecogenomic sensor vision. At that time, there were only two systems that had succeeded in integrating the steps of sample collection and molecular analytical analyses into remotely operable, subsurface capable, ocean-deployable instruments: the Autonomous Microbial Genosensor (AMG) and the Environmental Sample Processor (ESP). Each of these devices met the conceptual definition an ecogenomic sensor, but neither was as highly evolved as that implied in *Figure 1*. Despite their limitations, the AMG and ESP provided a glimpse into research efforts that were aimed at fielding

Figure 2 Photo of the second-generation (2G) ESP. The instrument is shown fitted (on top) with a surface-mooring pressure housing endcap (see *Figure 5*). The bulk of the instrument's electromechanical systems are on the top half of the device; visible at back in the mid-lower left side is a portion of the rotating carousel that holds pucks as shown in *Figure 3*. The black base is hollow and used to capture waste fluids. Reagents used for sample processing (not shown) are attached to the frame. The ESP is made available through Spyglass Biosecurity in partnership with McLANE Research Laboratories. The ESP is ~0.5-m diameter and 1-m tall. The instrument is protected under US Patent No. 6187530. Photo by © McLANE Research Laboratories, Inc.

automated molecular detection systems in an ocean setting. They also illustrated the maturity gap between molecular analytical instruments designed for ocean use versus the plethora of commercial systems aimed at the biomedical, food safety and military markets (Scholin, 2010). As time moved on, the ESP was shown to support a diverse set of detection chemistries and it was proven to be capable of operating in coastal, deep-sea and open ocean environments. In that way, the ESP came to exemplify an emergent ecogenomic sensor and served to highlight the potential for further development and application of that class of instrument.

The ESP

System Overview

Work on the ESP began in the mid-1990s. It was originally built as an experimental system to help define both the technological and operational elements that underlie the ecogenomic sensor concept. Accounts detailing the early fabrication and use of the ESP are summarized elsewhere (Scholin *et al.*, 2008; Roman *et al.*, 2007). It is a robotic device that was conceived around three, major functional elements: external sampling modules, a core sample processor ("core ESP"; Figure 2) and analytical modules (as detailed in Scholin *et al.*, 2009). These three components allow for a cascade of autonomous operations from acquiring a coarse-screened, multi-L sample from surface to deep ocean waters, to the detection and quantification of specific nucleic acid sequences or other biotic materials on a microliter scale.

Within the core ESP, "pucks" (Figure 3) are used to compartmentalize various steps associated with sample acquisition and processing. Pucks are stored in a rotating carousel. Robotic mechanisms serve to move pucks into and out of different sample processing stations, with each station being dedicated to specific functions like sample concentration, chemical processing or probe array imaging. Pucks can be configured to contain a variety of filters, or chemically reactive media depending on the specific application required. By programming a sequence of actions that coordinate moving pucks through the various stations in concert with actuating valves for collecting a sample and pumping reagents, the ESP functions autonomously to detect a variety of organisms and substances they produce (Roman *et al.*, 2007).

Sample Processing Capabilities

Initially, the ESP's design was heavily influenced by methods geared toward detection of groups of organisms and specific species based on ribosomal ribonucleic acid (rRNA) sequences. Such "signature sequences" can be detected within intact cells or through a variety of cell-free methods wherein target molecules are liberated into solution (e.g., Scholin *et al.*, 1996). By detecting and quantifying rRNA molecules one can ascertain the presence of certain species and under certain circumstances estimate their abundance as well (e.g., Metfies *et al.*, 2006 and references therein).

The sandwich hybridization assay (SHA) is a cell-free method that allows for rapid detection of rRNA (Van Ness and Chen, 1991; Marin and Scholin, 2010). When applied in a DNA probe array format, the technique provides a means to sense the presence of a variety of organisms simultaneously

Figure 3 Pucks used in the ESP to compartmentalize collection and processing of samples. All pucks conform to the same overall size and shape (~30 mm diameter × 17 mm tall) so that robotic systems used to move them are standardized against a constant form factor. Shown from left to right are pucks for sample collection and homogenization (for use with conventional membrane filters), large and small format probe arrays (arrays printed on 25-mm or 12-mm diameter membranes, respectively), sample preservation (for use with conventional membrane filters), and high-volume sample collection and homogenizing (for use with sintered wafer filters). Scale at the bottom is in inches. Photo by © McLANE Research Laboratories, Inc.

in a single test (e.g., Jones *et al.*, 2007; Greenfield *et al.*, 2008; Preston *et al.*, 2009; **Figure 4(a)**). Reagents for SHA are stored as liquids that are held in flexible bags or other containers attached to the core instrument; these chemicals are stable for many months over a wide temperature range. Similar to the SHA is a sample processing procedure that employs protein probe arrays (Doucette *et al.*, 2009). Protein probe arrays make it possible to use antibody-based techniques to quantify the presence of target molecules other than rRNA. Historically, the DNA and protein probe arrays as used in the ESP have been used in tandem to detect harmful algae and toxins they produce. The presence and abundance of molecules detected by both types of assays is conveyed via a chemiluminescent reaction. A camera captures an image of the light emitted from a puck (**Figure 3**), thus recording the intensity of reactions associated with each sensing element on a probe array. The entire process, from collection of a live

sample to broadcast of an imaged array, takes approximately 2 h (Scholin *et al.*, 2009; <http://www.mbari.org/ESP/espworks.htm>).

The fluid handling system of the core ESP is capable of manipulating volumes down to roughly 100 μL . Although this is appropriate for demonstrating the use of the probe arrays, for example, that level of resolution precludes application of other desirable detection technologies, such as quantitative PCR (qPCR), that for a number of reasons demand precise fluid handling at the scale of at least 1 μL (Scholin, 2010). To meet the latter need, a separate fluid handling system was added. This ancillary system is referred to as the “microfluidic block,” or MFB; it bolts to the core instrument and connects via single electrical and fluidic interfaces. The core ESP functions to concentrate and condition samples prior to passage to the MFB. The MFB then acts as a take-off point for distributing very small volumes of sample extracts and reagents to one or

Figure 4 Examples showing results of DNA probe array (top) and quantitative PCR assays (bottom) obtained from two different periods during a field deployment of an ESP fitted with a MFB/PCR module. Probes targeting specific ribosomal RNA sequences (rRNA) indicative of various bacterioplankton are arranged horizontally; positive controls for verifying array orientation are arranged vertically (actual array size is ~10-mm tall by 5-mm wide, roughly half of the full large-array format used in the puck); darker spots indicate more intense reaction (more abundant target). Changes in the microbial community structure are apparent between the two sample periods. Highlighted on the arrays are rRNA probes indicative of SAR 11 (red) and marine crenarchaea (blue). The qPCR plots show reactions for the corresponding rRNA gene sequences along with a functional gene (RuBisCo) from *Synechococcus* (green) and an internal positive control (IPC; black). From this raw data one can determine that the marine crenarchaea were more abundant on May 15 than on May 29, 2009 (etc.). See Preston *et al.* (2011) for more details.

Figure 5 ESP surface mooring. The ESP is moored to the ocean bottom as illustrated in (a). The ESP is mounted on a subsurface platform (b) that carries batteries (in the orange boxes) and other ocean sensors; a electromechanical cable allows for communications and connection with the surface buoy. The assembly shown in (b) has a cutaway view of the pressure housing, revealing the ESP inside. Divers inspect the subsurface assembly during a test tank trial (c). Photo by Todd Walsh © 2006 MBARI.

Figure 6 ESP open-ocean drifter. A surface float holds the ESP at a fixed depth from the surface via a electromechanical cable (a). As with the surface mooring, the ESP is mounted on a subsurface platform that carries other ocean sensors. Photo showing the deployment of the drifter surface float (b) and the freely drifting assembly with the R/V Western Flyer in the background (c). Photo by Philip Sammet © 2010 MBARI.

more molecular detection systems (or analytical modules as per Scholin *et al.*, 2009).

A DNA extraction system and flow-through, two-color (i.e., two optical channels), real-time PCR machine was recently incorporated into the MFB (Preston *et al.*, 2011; Robidart *et al.*, 2011). The MFB/PCR module permits application of a variety of polymerase enzyme master mixes, primer/probe combinations and assay controls. Presently, up to six qPCR reactions can be applied to a given sample at any one time. Reagents used with those assays are stored as liquids and have proven to be stable at room temperature for up to five months (the longest test conducted to date). The SHA and qPCR techniques can be applied to the same sample so that both an rRNA community profile and select gene abundances can be ascertained (e.g., Figure 4). As before, it takes approximately 2 h between collecting a live sample to recording an array image; results from each qPCR reaction are available roughly every 2 h thereafter.

Complementing the real-time data provided by the probe arrays and qPCR is the core ESP's ability to preserve discrete samples for subsequent laboratory-based analyses. Preserving samples *in situ* has a number of applications. That capability was originally motivated by a desire to validate trends in species abundance observed during field deployments (e.g., Greenfield *et al.*, 2006). It also provides additional sample materials that can be used to support analyses that are not yet appropriate for use with an instrument like the ESP (e.g., nucleic acid sequencing (Ottesen *et al.*, 2011), proteomics research (Saito *et al.*, 2011)).

Operational Uses

The ESP has been deployed on a variety of platforms including coastal moorings (Figure 5), an open ocean drifter (Figure 6), and a 4000 m-rated benthic lander for delivering the instrument to the seafloor (Figure 7). When deployed, the ESP is bundled with sensors for assessing basic ocean properties like temperature, salinity, chlorophyll (etc.) so that samples collected, and the assay results obtained, can be referenced against prevailing environmental conditions. The ESP can be operated in a standalone mode or as part of a larger ocean-observing system (e.g., Ryan *et al.*, 2011). Two-way communications with the machine are achieved using a radio or acoustic modem, satellite link or direct (wired) network connection.

Figure 7 Free-fall vehicle for deploying the ESP to 4000-m depth. As illustrated in a cutaway view (a), the ESP is mounted in spherical pressure housing that is attached to a larger structure for free-fall deployment to the ocean bottom. An external sampling module (two tall cylinders at left) allows for inhaling up to 10 l of water at a time prior to making it available to the core ESP; a hose emanating from the sampling module directs sample intake from precise locations on the seafloor. The author stands with the D-ESP prior to its deployment (b); the lander holds a variety of other sensors, batteries, and data telemetry systems. The D-ESP as seen by remotely operated vehicle atop a carbonate mound at 890-m depth off Southern California (c); the mound vents methane gas, and the surrounding waters are enriched with methane-oxidizing bacteria. Copyright by © 2010 MBARI.

To date, most applications of the ESP have focused on surface waters with foci being bacterioplankton, harmful algal blooms (HABs) and invertebrates (*see* Sample Processing Capabilities). Individual instruments have been used to detect one or all of those species during coastal mooring deployments (**Figure 5**) each of which lasts roughly 30 days. Most of the work has concentrated on feasibility studies and methods demonstrations. Recently, progress has been made in utilizing the ESP to reveal novel marine microbial community dynamics in coastal waters (Preston *et al.*, 2011; Robidart *et al.*, 2011) and patchiness of species responsible for HABs

(Ryan *et al.*, 2011). Other studies have focused on testing specific hypotheses regarding HAB initiation and evaluating different strategies for detecting small invertebrates. Academic and government agencies are presently evaluating the utility of the ESP to carry out water-quality assessments associated with sewage effluents.

Oceanic microbial community structure and function is generally referenced against environmental conditions that are assessed at the instant samples are collected. However, the biological community collected at any one time is derived from past as well as current conditions. Consequently, there is

an inherent difficulty in establishing detailed cause-and-effect relationships since the history of the community or population in question is generally not known. For this reason, a platform that allows the ESP to drift freely in the open ocean was created (Figure 6). So far, the drifting ESP has been deployed only for short periods (up to 10 days as of 2011), but it runs continuously throughout that period to yield very-high-resolution time-series data. Such deployments have recently taken place along the central California coast (Ottesen *et al.*, unpublished) and in waters north of Hawaii (Robidart *et al.*, unpublished). A long-term goal is to translate this experimental system into one that is capable of actively identifying, tracking, and sampling coherent microbial populations so that changes in their community structure and gene expression can be assessed with respect to both space and time domains.

The advent of cabled observatories as depicted in Figure 1 is opening a new door for operating novel sensor systems on the seafloor. With that are new opportunities for assessing microbial community structure and function in particular locations and on temporal scales not achievable previously. These developments spurred on the idea for a platform that would allow the core ESP to operate in the deep sea (Figure 7), in particular at sites dominated by hydrothermal vents, hydrocarbon seeps, and other features of intense microbiological interest. A special pressure housing and external sampling module that isolates the core ESP from such extreme environments was thus devised, allowing the instrument to function in a deep-ocean setting as it does in surface waters. It is expected that the deep-sea ESP will operate for periods up to 1 year between servicing intervals when powered by an ocean bottom cable node.

Conclusions and Future Prospects

Ecogenomic sensors are fast becoming a reality. With the expansion of coastal and global ocean sensing systems, opportunities for developing and fielding ecogenomic sensors should increase. For the first time in the history of the ocean sciences, it is realistic to conceive of carrying out interactive experiments remotely *in situ* from a molecular biological perspective along the lines of that conceptualized in Figure 1. Recent progress made in bringing the ESP to operational status has helped lend credibility to that vision, but much more remains to be done if ecogenomic sensors are to become commonplace in the environmental sciences.

A primary need is to develop a new generation of these devices that are much smaller and mechanically less complex than the current ESP system. Once that type of ecogenomic sensor exists, it is likely that the push will be to integrate such sensors with mobile platforms such as autonomous underwater vehicles (AUVs). If that can be accomplished, then researchers will have an ability to collect and analyze discrete samples in response to changing environmental conditions without the current restrictions imposed by traditional shipboard operations, much in the same way that profiling floats equipped with chemical sensors have revolutionized our ability to observe the interior of the global ocean (e.g., Johnson *et al.*, 2010). No longer is it a pipe dream to imagine fleets of mobile systems working cooperatively to identify

specific communities of microorganisms and follow them over time (cf. Ryan *et al.*, 2010; Zhang *et al.*, 2010, 2011), revealing time and space relationships that ultimately unite environmental forcing and organism function and activity (Zehr *et al.*, 2011; Figure 8).

From an engineering perspective, future development of ecogenomic sensors should be driven by a clear set of science or monitoring requirements rather than what may be possible to achieve technologically (Scholin, 2010). For example, ecogenomic sensors may be needed on moorings, cabled networks, profiling systems, near the surface, or at great depth. They may be readily accessible or in very remote locations, highly configurable, or very limited in their functionality. Accordingly, operations and maintenance requirements as well as system costs will vary greatly. Proxy measurements and modeling techniques will be needed to a greater or lesser extent to interpolate between a discrete and limited set of sensors collecting molecular analytical data. Although some common themes will almost certainly emerge, it is highly doubtful that a single design will meet all the ecogenomic sensing needs articulated by researchers and resource managers.

Glossary

Exoenzymes Digestive enzymes excreted by fungi into the environment to digest materials externally.

Fruiting body Sexual reproductive structure of a fungus.

Fungus A member of the kingdom Fungi. Members of this kingdom are heterotrophic (requiring a preformed organic source, i.e., not able to make their own food), eukaryotic, have walls of chitin, and reproduce by means of spores.

Hyphae The feeding (vegetative) threads of most fungi. The hyphae of one organism are sometimes referred to as a mycelium.

Mushroom Vernacular word for a large, fleshy fruiting body consisting of a cap with gills or pores on the undersurface (or sometimes flat or with teeth or folds), usually on a stalk, and producing sexual spores. The term is usually reserved for members of the Basidiomycota. A poisonous mushroom is sometimes called a toadstool.

Mutualism Two organisms living together for the mutual benefit of both.

Mycorrhiza Part of a mutualistic relationship between a fungus and a host plant. The two types are ectomycorrhizae (usually a Basidiomycota, but sometimes an Ascomycota) in which hyphae aggregate as an extra surface around roots of the plant, and endomycorrhizae (a Glomeromycota), in which no sheath is formed, but nutrient transfer occurs with the aid of highly branched arbuscules.

Parasite Organism that obtains its nutrition from a living host, and in so doing harms the host.

Spore One- to several-celled propagule of totipotent cytoplasm with cell walls, produced by cell division with concomitant meiosis or mitosis, that may serve for dispersal or overseasoning, but that does not contain an embryo.

Introduction

When someone mentions “fungi” you may think immediately of mushrooms on pizza or maybe moldy food in your refrigerator. But in fact fungi are everywhere and affect our lives every day, from edible mushrooms to industrially important products to plant helpers, plant pathogens, and human diseases. Many fungi are detrimental in causing a large number of plant diseases that result in the loss of billions of dollars worth of economic crops each year. They also cause a number of animal diseases, including many human maladies. On the other hand, there is a long and rapidly growing list of useful fungi. Fungi have been used in the preparation of foods and beverages for thousands of years, and there are many mushrooms that are edible. Industry has used other fungi in the manufacture of many valuable organic compounds, including organic acids, vitamins, antibiotics, and hormones. They have been used in the research laboratory to study metabolic pathways, mineral nutrition, genetics, and a variety of other problems. But perhaps their greatest contribution has been, and continues to be, their role in recycling carbon and other essential elements in the ecosystem. Because all fungi are heterotrophic (*see* Fungi in the Environment), they rely on organic material, either living or dead, as a source of energy. Thus, many are excellent scavengers in nature, breaking down dead animal and vegetable material into simpler compounds that become available to other members of the ecosystem.

“Mycology” comes from the Greek words *mykos*, which means “fungi,” and “-logy,” which means “the study of.” Mycologists study many aspects of the biology of fungi, usually starting with their systematics, taxonomy, and classification, and continuing on to their physiology, ecology, pathology,

evolution, genetics, and molecular biology. There are quite a few fields of applied mycology, such as plant pathology, human pathology, fermentation, mushroom cultivation, and many other fields.

What are Fungi?

Characteristics of Fungi That Separate Them from the Other Kingdoms

The most significant characteristics of fungi that place them apart from the plant, animal, and other kingdoms are the following:

- Fungi are eukaryotic.
- They are nonvascular organisms, meaning they have no specialized transport tissues.
- Most reproduce by means of spores, usually wind-disseminated, and occasionally by insects in some species.
- Both sexual (meiotic) and asexual (mitotic) spores may be produced, depending on the species and conditions.
- Fungi are typically not motile, although a few (e.g., chytrids) have a motile phase.
- Like plants, sexually reproducing fungi have an alternation of generations, although the generations may be different from those of plants.
- The fungal vegetative body may be unicellular (yeasts) or, more often, composed of microscopic threads called hyphae.
- Fungal cell walls are similar in structure to those of plants but differ in chemical composition – fungi cell walls are composed mostly of chitin, which are β -1,4 linkages of

Table 1 Taxonomic endings for the fungi

<i>Taxonomic level</i>	<i>Taxonomic ending</i>	<i>White button pizza mushroom</i>	<i>The morel</i>
Domain	Eukarya	Eukarya	Eukarya
Kingdom	Fungi	Fungi	Fungi
Phylum	-mycota	Basidiomycota	Ascomycota
Class	-mycetes	Hymenomycetes	Discomycetes
Order	-ales	Agaricales	Pezizales
Family	-aceae	Agaricaceae	Morchellaceae
Genus	–	<i>Agaricus</i>	<i>Morchella</i>
Species	–	<i>Agaricus bisporus</i>	<i>Morchella esculenta</i>

n-acetylglucosamine. In contrast, plant cell walls are composed mostly of cellulose, which are β -1,4 linkages of glucose. Many plants also contain lignin in their secondary walls.

- Fungal cytoplasmic ultrastructure is broadly similar to that of plant cells, but differs significantly in the kinds of organelles and their structures.
- Fungi are heterotrophic (i.e., “other feeding” in that they must feed on preformed organic material), not autotrophic (i.e., “self-feeding” in that they make their own food by photosynthesis, like most plants and algae).
- Unlike animals (which are also heterotrophic), which ingest and then digest, fungi first digest and then ingest. Fungi produce exoenzymes to accomplish this.
- Most fungi store their food as glycogen (like animals) – plants store food as starch.
- Fungal cell membranes have a unique sterol, ergosterol, which replaces the cholesterol found in mammalian cell membranes.
- The lysine biosynthesis pathway in fungi is different.
- The microtubule protein formed during nuclear division is different from that of all other organisms.
- Most fungi have very small nuclei, with little repetitive DNA, usually with few chromosomes.
- Mitosis and meiosis are generally accomplished without dissolution of the nuclear envelope.

There are about 75,000 named species of fungi and this is believed to be about 5% of the total number of species that exist in nature. If this is the case, 95% of all fungal species are unknown to science and do not yet have names.

In the outdated two-kingdom system, fungi were included in the plant kingdom, as were almost all walled organisms that are not motile. In almost all systematic schemes today, the heterotrophic, eukaryotic fungi are placed in their own kingdom, cleverly called the kingdom Fungi (Alexopoulos *et al.*, 1996).

The eukaryotes, organisms with nuclei and membrane-bound organelles, can be divided into five kingdoms: Fungi, Plantae, Animalia, Protista, and Stramenopila. Recent DNA evidence suggests that fungi are more closely related to animals than to plants. Prokaryotes, without nuclei and membrane-bound organelles, include the Bacteria and the Archaea.

As with all taxonomy, the names of various taxa of fungi each have a specific ending that refers to their taxonomic level. The fungal kingdom has its own endings for many taxa; these include a suffix containing -myc. It is of considerable advantage to be familiar with these endings so that one knows

immediately what taxonomic level is being referred to when confronted with a particular name. The names of fungi are “regulated” by the International Code of Nomenclature for Algae, Fungi, and Plants, and thus endings for the order and family levels are the same as those of plants (Table 1).

Fungal Roles in the Ecosystem

Lack of chlorophyll profoundly affects the lifestyle of fungi. Since they are not dependent on light, they can occupy dark habitats and can grow in any direction. The exoenzymes allow them to invade the interior of a substrate with absorptive filaments. Fungi may gain their nutrition from dead organisms, in which case they are called saprophytes. Some fungi derive their nutrition from living organisms; these are called symbionts. Symbionts can be further divided on the basis of whether or not they harm their host. Parasites cause harm to the host, whereas mutualists engage in a reciprocally beneficial association with their host. These categories are further described in the section Fungi in the Environment.

Importance of Studying Fungal Biodiversity

Fungi affect human lives in many and varied ways, so it is important to know something about the fungi to be able to control or exploit them for our own purposes. For example, more than 90% of known fungal species have never been screened for antibiotics or other useful compounds. However, even more important is the role that fungi play in the ecosystem. They are a vital part of the links in the food web as decomposers and pathogens and are important in grassland and forest ecosystems alike. Fungi have many different kinds of associations with other organisms, both living and dead. To learn more about the impact that fungi have on our lives, we must learn a lot more about them.

Many fungi are harmful to human interests. They can cause human disease, either directly or through their toxins, including mycotoxins and mushroom poisons. They can also cause diseases of plants and animals (e.g., crops, fruit trees, farm animals). Very often fungi cause rot and contamination of foods – most of us probably have something green and moldy in the back of our refrigerator right now. They can destroy almost every kind of manufactured goods, with the exception of some plastics and some pesticides.

On the other hand, many fungi are very useful to humans (Hudler, 1998). Of course, there are many edible mushrooms. Yeasts have been used for baking and brewing for many

millennia. Antibiotics such as penicillin and cephalosporin are produced by fungi. The immunosuppressive antirejection transplant drug cyclosporine is produced by the ascomycete *Tolypocladium inflatum*. Steroids and hormones – and even birth control pills – are commercially produced by various fungi. Many organic acids are also commercially produced with fungi, for example, citric acid in cola and other soda pop products is produced by an *Aspergillus* species. Some gourmet cheeses such as Roquefort and other blue cheeses, brie, and camembert are fermented with certain *Penicillium* species. Stone-washed jeans, strange as it sounds, are actually softened by *Trichoderma* species, not by old ladies with babushkas beating the jeans on rocks in a stream. There are likely many more potential uses that have not yet been explored.

Fungi are also important experimental organisms. They are easily cultured, occupy little space, multiply rapidly, and have a short life cycle. Since they are eukaryotes and more closely related to animals, their study is more applicable to human problems than is the study of bacteria. Fungi are used to study metabolite pathways, to study growth, development, and differentiation, for determining mechanisms of cell division and development, and for microbial assays of vitamins and amino acids. Fungi are also important genetic tools; the “one gene one enzyme” theory in *Neurospora* won George W Beadle and Edward L Tatum the Nobel Prize for Physiology or Medicine in 1958. The first eukaryotic genome to have its DNA sequenced was that of the bakers’ and brewers’ yeast, *Saccharomyces cerevisiae*. Lee Hartwell and his colleagues used *Saccharomyces cerevisiae* to study mitosis genes and won the Nobel Prize in 2001.

How Fungi Grow

Biology of Hyphae and Yeast Forms

A fungus is more than just the visible mushroom structure. In fact the mushroom, more properly called a fruiting body, is a very small portion of the individual life cycle and is mainly used for reproduction. The major portion of the life cycle, or the vegetative growth form, in the great majority of fungi consists of a system of threadlike, walled, more or less cylindrical hyphae (singular, hypha) making up what is called a mycelium (plural, mycelia) (Figure 1). The Ascomycota and Basidiomycota have crosswalls called septa (singular, septum) separating compartments of the mycelium. An exceptional group is the yeasts, which consist of about 800 species that have a single-celled vegetative form. Note that yeast is a morphological term and has no taxonomic significance; yeasts and yeastlike forms can be found in all of the fungal phyla.

Exoenzymes and the Heterotrophic Lifestyle

Exoenzymes are the most important reason why fungi are so successful. Fungi excrete exoenzymes at the tips of the growing hyphae into their surrounding environment, where they play a major role in breaking down the substrate. Simpler molecules can then move into the hyphae by diffusion. Exoenzymes are the reason that fungi can grow into the center of a solid log,

Figure 1 Hyphae with dark-stained nuclei.

into your brain and lungs, or into a wide variety of other substrates.

Reproductive Biodiversity of Fungi

Fungal Life Cycles

The major events of any sexual life cycles are plasmogamy (cell and protoplast fusion), karyogamy (nuclear fusion), and meiosis (Figure 2). In most other familiar types of organisms, such as plants and animals, plasmogamy and karyogamy occur in rapid succession and are usually referred to as the single event of fertilization. In the fungi, however, plasmogamy and karyogamy may be separated in time by several minutes, several hours, several days, several years, or even several centuries! Thus the dikaryon, the $n + n$ stage, is a major component of the life cycle of fungi, especially in the Basidiomycota and Ascomycota. Nuclear cycles of all the members of the various phyla can be placed within this generalized nuclear cycle, differing mainly in the amount of time spent in each of the phases.

Besides this sexual cycle, many fungi, commonly called molds, can also reproduce asexually (mitotically) in the absence of karyogamy and meiosis. Many of them produce specialized structures that bear the asexual spores. As in much of biology, there is some “competing” terminology here – the asexual state is also known as the anamorph or mitosporic state. Asexual reproduction can take place at any point in the life cycle (haploid, diploid, or dikaryon), depending on the species and conditions. The sexual state is also known as the teleomorph or meiosporic state.

Phyla of fungi

Based primarily on variation in their sexual reproductive structures, the kingdom Fungi is usually divided into five major phyla.

- Chytridiomycota – sexual and asexual spores are motile, with posterior flagella.
- Zygomycota – sexual spores are thick-walled resting spores called zygospores, and asexual spores called sporangiospores

Figure 2 Generalized nuclear cycle for fungi.

(when present) are borne internally in structures called sporangia.

- Glomeromycota – form endomycorrhizae or AMF with 70% of the world's plants. Asexual reproduction is in the form of large underground spores, while sexual reproduction is unknown.
- Ascomycota – sexual spores (ascospores) are borne internally in a sac called an ascus, and asexual spores called conidia (when present) are borne externally on structures called conidiophores.
- Basidiomycota – sexual spores (basidiospores) are borne externally on a club-shaped structure called a basidium; most species do not have asexual spores, but when present they often take the form of conidia.

There is an additional group, the deuteromycetes, or “Fungi Imperfecti,” for which there is no known sexual state. Its members have affinities to members of at least three of the phyla, especially the Ascomycota.

Chytridiomycota

The Chytridiomycota, commonly called the chytrids, are a group of mostly water-inhabiting organisms, although some are plant pathogens. In aquatic environments they mostly form scanty filaments with sporangia. Some examples of the Chytridiomycota are *Allomyces*, a water mold, *Synchytrium endobioticum*, a pathogen of potato, and *Neocallimastix*, a chytrid that lives symbiotically in the gut of herbivores, such as cattle. *Batrachochytrium dendrobatidis* has been implicated as an infection associated with the worldwide decline in frog populations. This chytrid infects the skin of amphibians, rendering it too thick for water and gas exchange, and the frogs

die. Many species of frogs, particularly in the tropics, are thought to have gone extinct because of this quickly-spreading pathogen. It is unclear whether this is an introduced pathogen or whether it has always been there, but possibly becoming more prominent because of some environmental pollutant hampering frogs' immune systems.

There is some controversy about the placement of certain fungi into the Chytridiomycota, and there is some evidence to support that the multicellular forms, such as *Allomyces* and other members of the Blastocladales, should be placed in a new phylum, the Blastocladiomycota. Additionally, there is some molecular evidence that the cow chytrid and related species should be placed into a new phylum, the Neocallimastigomycota. Clearly, systematics of this group is in a state of flux as new evidence continues to be discovered.

Zygomycota

Commonly called the bread molds, the Zygomycota are terrestrial fungi whose fruiting bodies are mostly microscopic in nature, although their asexually produced sporangia can reach greater than 5 cm tall in some species (Figure 3). Under certain conditions they may sexually produce thick-walled resting spores called zygospores (Figure 4). Some, such as *Rhizopus*, *Mucor*, and *Phycomyces*, can grow on a wide variety of substrates, and a few can act as human pathogens. Many species, such as *Pilobolus*, inhabit dung and pass through the guts of herbivores to get into more dung.

Glomeromycota

Members of the Glomeromycota, are responsible for forming mutualistic associations called endomycorrhizae with the roots of about 70% of the world's plants. These endomycorrhizae are

Figure 3 *Rhizopus* sporangia.

Figure 4 *Rhizopus* zygospore between suspensors.

Figure 7 Basidium showing the four basidiospores produced by meiosis and pinching off of the spores from the basidium.

also known as arbuscular mycorrhizal fungi, abbreviated AMF. Glomeromycota form relatively large (up to 1 mm) asexual spores in the soil, but sexual reproduction is unknown. The Glomeromycota were once considered to belong to the order Glomerales (= Glomales) of the Zygomycota, but molecular data, along with the unique morphology and ecological niche, have confirmed that the Glomeromycota should be considered a separate phylum. See the section Mycorrhizae below for further discussion.

Ascomycota

The Ascomycota bear their sexual spores (ascospores) internally in sacs called asci, which are usually cylindrical. Many members also form conidia as asexual spores. Familiar members of this phylum include the morels (**Figures 5 and 6**) (Weber, 1988; Kuo, 2005) and other cup and saddle fungi, truffles, powdery mildews, the industrial yeast *Saccharomyces cerevisiae*, the incitant of chestnut blight (*Cryphonectria parasitica*), the cause of Dutch elm disease (*Ophiostoma ulmi*), and a

variety of other plant pathogens. About 1/3 to 1/2 of the species of Ascomycota are associated with algae or cyanobacteria in the form of lichens (*see* Lichens), while a growing number of genera, such as *Morchella*, *Helvella*, and *Leotia*, are being discovered to form ectomycorrhizae with host plants.

Basidiomycota

The Basidiomycota bear their sexual spores externally on a usually club-shaped structure called a basidium, which is often borne on or in a fruiting body called a basidiocarp or basidiome (**Figure 7**). This phylum includes the well-known mushrooms, both edible and poisonous, as well as boletes, puffballs, shelf fungi, jelly fungi, and coral fungi (**Figure 8**). Many of the most prized edible species, such as king boletes,

matsutake, and chanterelles, form ectomycorrhizae with host plants. (*see* Mycorrhizae) The species that produce fruiting bodies exhibit various methods of increasing their surface area, as discussed in the section Surface Area and Reproduction.

The Basidiomycota also include perhaps the most important crop plant pathogens, the rusts and the smuts, which are responsible for billions of US dollars every year in lost yield. These fungi do not produce macroscopic fruiting bodies, but instead bear their spores on the stems, leaves, and flowers of host plants. However, remember that the mycelium is internal and “sucks” the nutrients out of the plant using its exoenzymes. Effects on the plant range from a reduced yield to death. Rusts are also interesting because of their very complicated life cycles, often requiring two unrelated host species to complete their growth stages. For example, the agent of

Figure 8 (a) *Armillaria nabsnona*, (b) *Tremella reticulata*, (c) *Trametes versicolor*, (d) *Pulcherricium caeruleum*.

Figure 9 *Aspergillus* conidia.

Figure 10 Jell-O mold, a favorite dish for picnics.

black stem rust of wheat alternates between wheat and barley, taking a year to complete its life cycle.

“Deuteromycetes,” the Fungi Imperfecti

The deuteromycetes, commonly called molds, are “second-class” fungi that have no known sexual state in their life cycle, and thus reproduce only by producing spores *via* mitosis. This asexual state is also called the anamorph state. Despite its “-mycetes” ending the deuteromycetes are not a class; rather this term is now used as a common name for this dumping-ground group of fungi. About 90% of these have affinities to the Ascomycota. Most food spoilage (Figures 9 and 10) and fungal human diseases are caused by members of this group. They are also known as the fungi imperfecti, because of their “imperfect” lack of sex. When the “perfect state” of one of these organisms is discovered, as happens every year, the fungus is more properly classified with the teleomorph name, although in practicality, like for people, it is difficult to remember to switch to their “married” name. Notice that this group is not classified as one of the phyla. It is just a loose assemblage of organisms that we have not been sure where to place accurately in the taxonomic order. Although we can accurately place most of these fungi into phyla using molecular biology techniques such as PCR and DNA sequencing, mycologists maintain this group and its genera for convenience and tradition (St-Germain and Summerbell, 1996).

Excluded Taxa: Former Members of the Kingdom Fungi

The organisms included here were once considered to be true fungi, but have been excluded because they do not exactly fit our modern classification scheme of the true fungi in various

ways. They are now considered to belong in other kingdoms, such as Protista or Stramenopila.

Oomycota: Water Molds and Downy Mildews

The Oomycota have been excluded from the kingdom Fungi primarily because their cell walls are made of cellulose rather than chitin. They also have swimming zoospores with two flagella (one whiplash and one tinsel), large nuclei, large egglike oospores, and various other nonfungal-like features. They are closely related to the brown algae (kelps) and diatoms, but of course lack chloroplasts. These organisms are now placed as heterokonts in the kingdom Stramenopila (or the catch-all dumping-ground kingdom Protista according to some authors). Ecologically many of its members act like fungi, especially the plant pathogens. *Phytophthora infestans* causes a disease called late blight of potato, which was the cause of the Irish potato famine in the 1840s, in which more than a million Irish people perished and another million emigrated. The downy mildews *Peronospora parasitica* and *Plasmopara viticola* cause diseases of members of the cabbage family and of grapes, respectively. *Pythium* species cause damping-off disease of seedlings in agricultural practice. However, many other species are innocuous saprophytes that decompose debris in water. A few of these so-called water molds (some species of *Saprolegnia* and *Achlya*) are opportunistic fish parasites, especially in aquariums and fish hatcheries (Figures 11 and 12). They are a particular problem in trout and salmon hatcheries.

Myxomycota: True Slime Molds

The Myxomycota are the true slime molds, also known as the plasmodial slime molds, and are considered members of the kingdom Protista or Amoebozoa, closely allied with other garden-variety amoebae. They exist in nature as a plasmodium – a blob of protoplasm without cell walls and only a cell membrane to keep everything in (Figure 13). It is really just a large amoeba and feeds much the same way, by engulfing its food (mostly bacteria) with pseudopodia, in a process called phagocytosis. So the slime mold ingests its food, then digests it. True fungi have a cell wall and digest their food with

Figure 11 *Saprolegnia* oogonium containing oospores.

Figure 12 *Saprolegnia* sporangium containing small zoospores.

Figure 13 Plasmodium of a slime mold.

Figure 14 Some slime mold fruiting structures (a) *Lycogala epidendrum*, (b) *Comatricha typhoides*, (c) *Badhamia utricularia*, (d) *Dictydium cancellatum*.

exoenzymes before ingesting it. When the plasmodium runs out of food, it can form fruiting bodies. Most slime mold fruiting bodies are quite small, 1–4 mm in height (Figure 14), but some can be up to 25 cm in diameter. In such cases a large plasmodium, a meter or more diameter, may be seen crawling along the ground, inspiring science fiction movies such as “The Blob”. These slime molds have been traditionally studied by mycologists because their small, delicate fruiting bodies tend to be fungal in appearance. Most slime mold fruiting bodies are quite beautiful, especially under a dissecting microscope.

Dictyosteliomycota: Cellular Slime Molds

The Dictyosteliomycota are the cellular slime molds or “social amoebae” and are among the most bizarre of microorganisms (Raper, 1984). These members of the Protista or Amoebozoa are free-living amoebae with no cell walls, indistinguishable from garden-variety amoebae until they begin to run out of food. At that point they signal to one another using cyclic AMP (a small nucleotide molecule) and begin to aggregate to form a “slug” or pseudoplasmodium. This slug, composed of hundreds of amoebae, acts as a single organism (although it does not feed) and can actually migrate along a light or temperature gradient. Eventually the slug stops migrating, rounds up, and forms a sorus, a kind of sporangium containing spores on a stalk. Not all of the cells become spores; some of them “sacrifice” themselves to become stalk cells to raise the spores up into the air for a better position for wind dispersal. So

formerly free-living organisms act like a single organism for the good of the species. This “altruism” seems to fly in the face of the selfish gene hypothesis. Very strange indeed.

Plasmodiophoromycota: Endoparasitic Slime Molds

The Plasmodiophoromycota are an odd group of endoparasites that live almost their entire life cycle inside a cell of another organism. They lack cell walls in the assimilative state and reproduce by means of swimming spores (with two unequal whiplash flagella), the only part of their life cycle that does not occur inside a cell. *Plasmodiophora brassicae* causes club root in crucifers, and *Spongospora subterranea* causes powdery scab of potatoes. Scientists really do not know where to place these organisms taxonomically; they have been allied with the Oomycota, the Myxomycota, or various other protists, but in reality they are not closely related to any other known group of organisms. (Castlebury and Domier, 1998) No one is even yet sure what kingdom to place them in!

Surface Area and Reproduction

Many fungi have very specialized habitats. For example, the basidiomycete *Suillus americanus* can grow only in association with the eastern white pine, *Pinus strobus*. To infect a new white pine, the immobile mycelium of the fungus must produce spores to move to a new host. These spores are carried by the wind, not by some specific insect or other animal vector. Thus the fungus must produce enormous numbers of spores so that

Figure 15 Different ways of increasing the surface area for bearing spores. Clockwise from upper left: pores, upright branches (coral), teeth, and gills.

a few of them will land on the “correct” substrate. The underside of the *Suillus* mushroom has small pores that are lined with microscopic spores. This increases the surface area for bearing spores by more than 100 times. More commonly, mushrooms have gills underneath the cap to increase surface area. Other fungi increase their surface area by forming upright coral-like branches, whereas others form downward-pointing teeth or spines (Figure 15). Others (not shown) have blunt ridges and some have folds, and some increase the time of sporulation rather than the spore-bearing physical space. Analogous surface area modifications are made by members of other phyla of fungi.

Fungi in the Environment

Fungi occupy many different niches in the environment, although any one species usually occupies only a single niche. Many niches have not yet been explored for fungi, which is the major reason why mycologists believe there are high numbers of fungi yet to be discovered. Fungi can be divided into groups based on their nutritional status and the nature of their relationship with their host. Saprophytes use nonliving organic material and are important scavengers in ecosystems. Along with bacteria, fungi are important in recycling carbon,

nitrogen, and essential mineral nutrients. Parasites use organic material from living organisms, harming them in some way. Their hosts range from single-celled diatoms to other fungi, plants, animals, and humans. Fungi are the major parasites (pathogens) of plants. Mutualists are fungi that have a reciprocally beneficial relationship with other living organisms, in which both organisms benefit. The three main types of mutualistic associations involving fungi are mycorrhizae, which are associations of fungi with plants roots, lichens, associations with algae or cyanobacteria and endophytes, associations inside leaves, stems, and roots of plants. There are also a few commensal fungi that use other organisms as merely a place to live; these fungi derive no nutrition from their host.

Fungi as Saprophytes

Along with bacteria, fungi are the major decomposers and recyclers in the environment. For every sort of dead material present, there is usually at least one fungus that can degrade that material. A few exceptions include some pesticides and some types of plastics; no fungi have yet developed exoenzymes capable of digesting these synthetic materials, although Gusse *et al.* (2006) have shown that biodegradation of some plastics is possible. Fungi are important in breaking down carbon- and nitrogen-containing compounds into

Figure 16 The disease triangle, showing the three factors that determine the disease severity.

Table 2 Types of plant diseases

Type of disease	Symptoms
Blight	Extensive necrosis and rapid death
Dieback	Dead branches protruding from apparently healthy tissue
Lesion	Localized cell death
Canker	Lesion on a woody stem
Rot	Extensive decay of tissue
Vascular wilt	Blockage of the vascular transport system, resulting in starvation or desiccation
Gall	Localized tumor like growth
Stunting	Reduction in overall growth size
Rusts	Rust-colored lesions on various parts of the plant
Smuts	Drastic malformations, usually of reproductive parts

Table 3 Some important forest pathogens

Pathogen	Disease
<i>Cryphonectria parasitica</i>	Chestnut blight
<i>Ophiostoma ulmi</i>	Dutch elm disease
<i>Discula destructiva</i>	Dogwood anthracnose
<i>Cronartium ribicola</i>	White pine blister rust
<i>Ceratocystis fagacearum</i>	Oak wilt
<i>Armillaria</i> spp., especially <i>A. mellea</i> and <i>A. solidipes</i>	<i>Armillaria</i> root rot

components that they and other organisms can use. Fungi are especially important in the breakdown of the wood components cellulose and lignin (discussed in the section Fermentation Products for Food Use).

Fungi as Plant Parasites

About 90% of plant diseases are caused by fungi, resulting in billions of dollars in crop and forest losses each year (Farr *et al.*, 1989). A parasite is referred to as a pathogen if it elicits a recognizable and persistent disease. The most severe pathogens are those that are imported accidentally from other continents and that cause severe problems with the native

populations and cultivated plants. The severity of any plant disease is determined by three factors, known as the disease triangle, consisting of the interaction of the host (conditions favoring susceptibility), pathogens (conditions affecting virulence), and the environment (conditions favoring disease) (Figure 16). All three factors must work in conjunction to produce a disease and determine its harshness.

Fungi in Crop Pathology

The science of plant pathology deals mostly with organisms, especially fungi, that cause plant disease. Plant diseases are generally classified on the basis of what kinds of symptoms occur in which part(s) of the plant (Table 2). Some important fungal pathogens of crop plants include *Puccinia graminis* (black stem rust of wheat), *Erysiphe graminis* (powdery mildew of grasses), *Claviceps purpurea* (ergot), and *Ustilago maydis* (corn smut).

Fungi in Forest Pathology

There have been a number of fungal diseases of forest trees that have caused great problems in North America (Table 3). Forest pathogens often need a longer time to kill their larger, perennial hosts, sometimes living inside the tree for several decades before the host finally succumbs.

Cryphonectria parasitica, *Ophiostoma ulmi*, and *Discula destructiva* are introduced pathogens that have devastated their hosts in North America. In their native Asia, these pathogens coevolved with their hosts and caused them only minor annoyance. However, when they were accidentally introduced into North America, either on live plants or on logs for sawing, the fungus escaped and subsequently devastated the North American tree species because there was not enough time for the host to develop resistance. *Cronartium ribicola*, *Ceratocystis fagacearum*, and *Armillaria* species are native American fungi, but they cause severe diseases nonetheless. A good pathogen does not kill its host right away, but keeps it alive as long as possible to continue deriving nutrients from it.

Fungi as Animal Parasites and Other Harmful Relationships

Fungi Affect Humans

Fungal effects on humans are classified by whether they can grow on the body (mycoses) or whether they cause problems by their ingestion. Mycetismus refers to the eating of poisonous mushrooms, while mycotoxicosis refers to the ingestion of toxins produced by the fungus, not involving eating the fungus itself. Mycoallergies, allergic reactions to fungi and their metabolites, are now defined enough that they should be considered a separate category.

Mycosis: Fungi Growing Directly on Human Tissues

There are a number of fungi that can grow directly on human tissue. Most of them require some debilitation of host defenses, especially the immune system. Fungal diseases have gained in importance over the last few decades because of increases in the numbers of such patients, including those with AIDS, people on corticosteroid therapy or immunosuppressive drugs (such as the transplant drug cyclosporine),

Table 4 Mycoses can be characterized by their location on the body

Type of mycosis	Location	Some diseases	Some fungi causing disease
Superficial mycoses	Infections of the hair shaft or dead outer layer of skin (stratum corneum)	Pityriasis versicolor, tinea nigra palmaris, piedra	<i>Malassezia furfur</i> , <i>Trichosporon beigelii</i> , <i>Cladosporium</i> , <i>Piedraia hortae</i>
Cutaneous mycoses	Dermatophytes – infections of skin, hair, and nails	Ringworm, jock itch, athlete's foot, tinea corporis, tinea capitis, and many others	<i>Microsporum</i> , <i>Trichophyton</i> , and <i>Epidermophyton</i> spp., occasionally a <i>Candida</i> sp.
Subcutaneous mycoses	Chronic localized infections of the skin and subcutaneous tissues	Sporotrichosis, chromoblastomycosis, phaeohyphomycosis	<i>Sporothrix schenckii</i> , <i>Phialophora</i> , <i>Cladosporium</i>
Systemic mycoses (deep mycoses), true human pathogens	Fungal infections of the body caused by dimorphic fungal pathogens, usually entering through the lungs	Histoplasmosis Blastomycosis Coccidioidomycosis Paracoccidioidomycosis	<i>Histoplasma capsulatum</i> <i>Blastomyces dermatitidis</i> <i>Coccidioides immitis</i> <i>Paracoccidioides brasiliensis</i>
Systemic mycoses, opportunistic pathogens	Fungal infections of the body caused by common fungi becoming pathogenic owing to patient debilitation	Aspergillosis Cryptococcosis Candidiasis Zygomycosis <i>Pneumocystis</i> pneumonia Penicilliosis	<i>Aspergillus</i> spp. <i>Cryptococcus neoformans</i> <i>Candida</i> spp. <i>Mucor</i> , <i>Rhizopus</i> <i>Pneumocystis carinii</i> <i>Penicillium marneffei</i>

diabetics, and people undergoing chemotherapy treatment for cancers.

About 175 human pathogens are recognized among the approximately 75,000 known species of fungi. Around 20 are regularly isolated from cutaneous infections (dermatophytes and yeasts), a dozen are associated with severe subcutaneous localized disease, and about 20 may cause systemic infections (Table 4). In addition, there are many opportunistic pathogens that cause disease in debilitated or immunosuppressed patients.

Probably the most common fungal infection in North America is yeast infection, caused by *Candida albicans*. Three out of every four women will get a yeast infection sometime in her lifetime. This yeast can grow on outside portions of the skin or in any area of the body that is moist and warm. It is especially prevalent in the genital area of women. Oddly enough *Candida* is part of the normal flora of the body and can be isolated from almost everyone at any time. Only when conditions get out of balance does the yeast flourish and cause disease.

However, the systemic true pathogens are the most feared, since they do not require a debilitation of the host defenses to become pathogenic. These dimorphic fungi get around host defenses by changing their form from a mycelium to a yeast upon change in temperature, thus evading even the healthiest of immune systems. Fortunately they are all geographically restricted. (see also Rippon, 1988).

Mycetismus: Eating Poisonous Mushrooms

Of the 75,000 species of fungi, there are about 250 species of delicious edible mushrooms and about 25 species that will kill you. In addition there are perhaps 200 species that will make you wish you were dead (Volk and Rippon 2001). Most of the other species are innocuous or unpleasant tasting. Some

people call poisonous mushrooms “toadstools,” a word probably derived from the old German *Tödstuhle*, meaning “death chair.” But how can you tell the difference? There is no easy way to tell if a mushroom is poisonous. Old wives’ or old husbands’ tales about silver spoons or whether it grows on wood or whether animals eat the mushrooms do not work! The only way to be sure if a mushroom is edible is to identify it to species by consulting books or knowledgeable persons (Barron, 1999; Bessette *et al.*, 1997; Lincoff, 1981; Gilbertson and Ryvarden 1987). The old saying is “there are old mushroom hunters, and there are bold mushrooms hunters, but there are no old, bold mushroom hunters.” The best way to learn about edible mushrooms is to join a local mushroom club. Do an internet web search for the North American Mycological Association for a list of these clubs. (Note: The pictures and descriptions in this article are NOT adequate to identify mushrooms for eating. We have a report of a woman who nearly died from eating wild mushrooms that she identified only from an encyclopedia drawing. Don’t let this be you! Be absolutely sure of your identifications!)

As shown in Table 5, unrelated species in various genera may contain the same toxin, and one or more toxin groups may be found in the same genus (Volk and Rippon, 2001). To complicate things further, many genera contain both poisonous and nonpoisonous species, although several genera are more or less homogeneous with respect to poisoning ability. Most species of fungi have not yet been analyzed for toxins (Benjamin, 1995). Evidence suggests that most mushroom toxins have not evolved for protection. For example, what good does it do a fungus such as *Amanita bisporigera*, known as the death angel, if an animal eats the mushroom and then dies two days later? The toxins appear to be merely waste products, usually from nitrogen metabolism, that happen to be poisonous to animals or humans.

Table 5 Seven major classes of mushroom toxins

<i>Class of toxin</i>	<i>Fungi where found</i>	<i>Main symptoms</i>	<i>Mode of action</i>
Cyclopeptides (amatoxins and phallotoxins)	<i>Amanita bisporigera</i> (Death angel), <i>A. phalloides</i> (destroying angel), <i>A. verna</i> , <i>A. ocreata</i> , <i>Galerina autumnalis</i> , and a few others	Violent cramps, diarrhea, nausea, jaundice, coma, death; it normally takes about 12–36 h for symptoms to appear	Attacks RNA polymerase in the liver, eventually destroys liver
Monomethyl hydrazine (gyromitrin)	<i>Gyromitra</i> species (false morels)	Nausea, vomiting, diarrhea, cramps, jaundice, convulsions, coma, death; cancers produced in mice	Similar in structure to solid rocket fuel, destroys red blood cells, attacks central nervous system
Coprine (tippler's bane)	<i>Coprinus atramentarius</i>	Hot, flushed, metallic taste, palpitation, vertigo, vomiting headache like a bad hangover	Blocks alcohol dehydrogenase so alcohol cannot be completely metabolized; similar in structure and function to Antabuse
Muscarine	<i>Inocybe</i> spp., <i>Clitocybe dealbata</i> (the "sweater")	Induces PSL (perspiration, salivation, lacrimation) symptoms, cramps, blurred vision; contraction of pupils, hypotension	Anticholinergic – antagonist to action of parasympathetic nerve fibers
Ibotenic acid, muscimol	<i>Amanita muscaria</i> and <i>A. pantherina</i>	Results in "expanded perception," talking to God, macropsia (perceiving objects as enlarged), rapid heartbeat, dry mouth	Hallucinogenic, psychoactive, action on nervous system, acts as a neuropeptide receptor
Psilocybin, psilocin, psychedelic mushrooms	Many <i>Psilocybe</i> spp., some <i>Panaeolus</i> spp.	Trancelike state induced, hallucinations	Serotonin (neurotransmitter) analog
Gastrointestinal irritants	Many different kinds, found in hundreds of species	Nausea, vomiting, no effect on other organs, most just cause discomfort or distress to varying degrees	Various, depending on the species of mushroom

Mycotoxins: Eating Toxins Produced by Fungi, not Necessarily from Eating the Fungi Themselves

Mycotoxins are usually produced by molds growing on foods. As the molds grow, they metabolize the food product and excrete their waste products back into the substrate. Some of these waste products are highly toxic, and when a person eats the toxin (even after cutting the mold off), there is usually some harm to the person. For example, the common contaminants *Aspergillus flavus* and *A. parasiticus* can produce aflatoxins, especially in peanuts. If you have ever eaten a whole peanut that tastes so bitter that you spat it out, it was probably contaminated with aflatoxin. This compound is highly carcinogenic at about 1 part per billion, and kills very rapidly at higher concentrations. There are legal limits for the amount of aflatoxin allowed in peanut butter sold in the United States. Many other toxins are produced by molds, especially in the genera *Aspergillus*, *Penicillium*, and *Fusarium*.

Mycoallergies, Allergic Reactions to Fungi and Their Metabolites

Allergies to fungi have been an increasingly recognized problem for many people. These allergies usually involve hypersensitivity to inhalation of the spores. One often hears about the "mold count" on a summer day. The main group of species that cause inhalation allergy problems are from the genus *Alternaria*, which has allergenic proteins on its surface.

Other kinds of fungal spores may germinate in the sinuses and secrete their waste products, which become a source of allergic reactions for other people. Allergic fungal sinusitis is now being successfully treated with antifungal drugs. Previous treatments suppressed the immune system, which allowed the fungi to grow better and produce more allergenic metabolites.

Sick Building Syndrome (SBS) often makes news headlines. People find molds growing in the homes, schools, and workplaces, where many people seem to develop symptoms such as headaches, nausea, and fatigue. The species that gets most of the blame for SBS is *Stachybotrys chartarum*, the so-called "black mold" (although there are dozens of common species of molds that are black). However there is yet no scientific evidence that *Stachybotrys* causes the symptoms that people describe. Further experimentation awaits.

Fungi Affect Other Animals

Nonhuman animals are affected by fungi in much the same way that humans are, with some differences in certain species. For example, dogs are susceptible to cyclopeptide poisoning while cats apparently are not. There are numerous other examples of this discrepancy – so do not pick and eat a mushroom just because you see an animal eat it. Another important point to consider is that you do not know what happened to that squirrel after it ate that mushroom.

Figure 17 Ectomycorrhizae on pine roots.

Animals are also affected by many of the same fungal diseases as are humans. For example, dogs are particularly susceptible to blastomycosis and are often used as a warning sentinel, like a canary in a mine, for alerting humans to possible risk.

Fungi as Mutualists with Other Organisms

Rather than being harmful, some fungi benefit their host in some way while receiving nutrients from them. The three most common mutualistic associations are mycorrhizae, an association between a fungus and the roots of a plant, lichens, associations between a fungus and either an alga or a cyanobacterium or both, and endophytes, associations of fungi inside the leaves, roots, and stems.

Mycorrhizae

According to Harley and Smith (1983), a mycorrhiza is defined as “an association between a fungus and a host plant in which destructive disintegration of the host does not occur and which is a prevalent and usual condition of the host plant in natural habitats and as such is very common and widespread.” *Myco*, of course, means “fungus,” and *rhiza* is “root,” so mycorrhiza literally means “fungus root.” More than 90% of plants in nature have a mycorrhizal symbiont. The only groups of plants that regularly lack mycorrhizae are some crucifers, sedges, and some legumes.

There are several types of mycorrhizae. In ectomycorrhizae, the fungus, usually a Basidiomycota or sometimes an Ascomycota, forms a sheath outside the root (Figure 17). Exchange of nutrients takes place in transfer cells called a Hartig net, which penetrates between the cells of the root cortex, but does not penetrate the cells themselves. In endomycorrhizae, also called vesicular arbuscular mycorrhizae (VAM) or sometimes

simply arbuscular mycorrhizae, no sheath is formed. This fungus is always a member of the Glomeromycota. Nutrient exchange takes place in highly branched hyphae called arbuscules, which penetrate into the cortical cells, but do not penetrate the cell membrane. Orchid mycorrhizae and ericoid mycorrhizae are special types that are found with plants in the Orchidaceae and the Ericaceae, respectively, and they differ significantly in their structure and life strategies.

In all types of mycorrhizae, hyphae extend from the root into the surrounding soil, greatly increasing the surface area for absorption of nutrients, particularly phosphate, nitrogen, and potassium. In return for shunting some of these nutrients into the plant, the fungus receives some sugars from plant photosynthesis. Thus both organisms benefit. Mycorrhizal fungi are abundantly represented in fossils from the Devonian and later periods and apparently coevolved with their hosts. It has been hypothesized that these fungi were necessary for the movement of water plants onto land.

As an interesting sidelight, there are also several hundred species of nonphotosynthetic plants (such as *Monotropa uniflora*, the Indian pipe) that get their energy as parasites of fungi that are mycorrhizal with photosynthetic plants. Radioactive carbon has been used to trace nutrient flow from the host plant through the mycorrhizal fungus and into the achlorophyllous plant. This type of ménage à trois is surprisingly common.

Endophytes

Only recently having been recognized for their importance, endophytes are microscopic fungi that live almost entirely within the leaves, roots, and stems of apparently healthy host plants. When they were discovered in leaves, they were assumed to be parasites, even though their presence caused no visible signs of infection. Although the hyphae are usually pervasive in the leaf, there is a lack of destruction of most cells and tissues. Further studies using radiolabeled compounds have shown that there was nutritional and chemical cycling between the host and fungus. Furthermore, both the fungus and the plant show increased vigor over plants without such relationships. In most cases that have been studied, the fungus receives sugars from the plant while producing bad-tasting toxins that deter herbivores from eating the plant. Thus the relationship should be classified as mutualistic, not parasitic. The best studied endophyte systems are in grasses and conifers (where endophytes apparently help the plants keep their needles longer), but endophytic fungi are probably found in most plants. Their significance in nature is greatly underappreciated.

Lichens

A lichen is a dual organism that consists of a mutualistic relationship between a fungus (the mycobiont) and an alga or cyanobacterium (the photobiont). Usually neither can survive on its own. Most of the fungi involved are Ascomycota, though a few are Basidiomycota. There are about 16,000 species of lichens, many of which can grow in very inhospitable environments – on rocks, sides and branches of trees, and gravestones, from the tropics to deserts to the Arctic (Figure 18). Lichens are very sensitive to air pollution, especially sulfur and nitrogen, and so they are natural indicators of

air quality. However, even under optimal conditions, lichens grow extremely slowly, usually 1–2 mm per year. The main ecological importance of lichens is their capacity to break down rocks into soil. They are an important food source for caribou and reindeer on the tundra. One of the first indications to the outside world that there had been a nuclear accident at Chernobyl, then in the Soviet Union, was the accumulation of radioactivity first in the lichens in Scandinavia, then in the milk given by the reindeer. Some lichens have been used as natural dyes, such as tweed and in litmus paper. In less enlightened times, a bright yellow lichen called *Letharia vulpina* was used by “pioneers” as a wolf poison.

Industrial Uses for Fungi

Mushroom Cultivation

The most widely available mushroom produced in the United States is the white button mushroom, *Agaricus bisporus* (Table 6). Commonly used on pizza and at salad bars, this mushroom is a secondary decomposer that is grown on

Figure 18 British soldier lichens, with their red caps for reproduction.

composted cow or horse manure. Some brown forms of *A. bisporus* are currently being cultivated; brown buttons are sold as crimini (or baby bellas) and opened mushrooms are sold as portabella mushrooms.

There are a number of steps in the commercial production of *Agaricus bisporus* (Volk, 2011):

- Manure is placed in large concrete “runways.”
- Composting (breakdown of the substrate into simpler components) occurs with the bacteria and fungi naturally present in the manure.
- Large machines turn the compost weekly, otherwise the center of the pile gets too hot because of metabolic heat and kills the composting bacteria and fungi. This also ensures even composting. The different species present naturally shift as composting progresses.
- After a couple weeks, the odorless compost is ready and is placed into large trays, 6 ft × 6 ft × 2 ft.
- Mycelium of *Agaricus* is inoculated into the composted substrate and allowed to grow for a few weeks.
- When the substrate is colonized, a sterile layer of nutrient-poor casing soil is placed over the top of the substrate.

A few weeks later, the mycelia send up rhizomorphs (hyphal aggregations) through the casing layer and form mushrooms on the surface. Contrary to popular belief, most mushrooms require light to initiate fruiting body formation. Light is often used as a signal to the mycelium that it is outside the substrate and that fruiting bodies can be formed. Some fungi form fruiting bodies in response to reaching outside air, where the concentration of carbon dioxide is lower. A few fungi fruit only when they run out of available nutrients. *Agaricus bisporus* has been bred so that it requires no light for fruiting.

There are a number of other specialty mushrooms, such as shiitake (Figure 19), oyster mushrooms, and lion’s mane mushrooms, that are being grown throughout the world and that are just becoming available in North American supermarkets (Volk *et al.*, 1997). Almost all these newly available mushrooms are primary decomposers of wood or other cellulose-containing substrates. These specialty mushrooms have gained in popularity in the past 10–20 years as consumers discover that these specialty mushrooms have great flavor and

Table 6 Some commonly cultivated edible mushrooms

Common name	Scientific name
White button pizza mushroom, crimini, portabella	<i>Agaricus bisporus</i>
Shiitake, shiang-gu	<i>Lentinula edodes</i>
Oyster mushrooms	<i>Pleurotus ostreatus</i> and other species
Enoki, velvet stem, winter mushroom	<i>Flammulina velutipes</i>
Hen-of-the-woods, Maitake, sheepshead	<i>Grifola frondosa</i>
Cloud ear, wood ear, black mushroom	<i>Auricularia auricula</i> ,
Chinese paddy straw mushroom	<i>Volvariella volvacea</i> ,
Pom-pon or Lion’s Mane	<i>Hericium erinaceus</i>
Reishi	<i>Ganoderma lucidum</i>
Wine cap	<i>Stropharia rugoso-annulata</i>
Morels	<i>Morchella</i> spp.

Figure 19 Shiitake mushrooms fruiting on an artificial log.

other interesting qualities. In Japan, China, and Korea, very little *Agaricus* is being grown (Stamets, 1993); growers concentrate on mushrooms with more robust flavors and interesting textures. Most of these specialty mushrooms are now grown on artificial sawdust logs by the following method:

- Place sawdust or wood chips with supplementary bran and millet and the appropriate amount of water into clear polypropylene bags. Autoclave or sterilize the filled bags, then allow to cool.
- Inoculate spawn (usually grain or sawdust with mycelium of the fungus growing on it) into medium. Mix thoroughly by hand or mechanically.
- Place bags in growth room. Allow spawn to grow rapidly through the substrate. Fungus colonizes bag in 30–60 days; sawdust is easier than solid wood to colonize because of increased surface area-to-volume ratio, abundance of air spaces, and uniform distribution of nutrients.
- During this period the loose medium is joined together into a coherent synthetic log.
- Depending on the species, at this time the plastic is removed, and the synthetic log can be handled like a natural log. Fruiting usually occurs within 90–120 days after inoculation.

Antibiotics and Other Drugs

Penicillin is the first antibiotic that was discovered to fight bacteria that cause human disease. It is naturally produced by *Penicillium chrysogenum* and related species as way of killing bacterial competitors in their environment. Cephalosporins are another class of antibiotics produced by *Acremonium* and related species. For a fungal infection of the fingernails and toenails, one prescribed drug is griseofulvin, produced by *Penicillium griseofulvum*. Ergotamine, produced by *Claviceps purpurea*, is used to facilitate the delivery of babies and can also be used to relieve migraine headaches. Another chemical found in *Claviceps* is a precursor to the hallucinogen LSD (lysergic acid diethylamide) that has the same effects as that illegal drug. The steroids in birth control pills are produced industrially by the fungus *Rhizopus nigricans*, as are the steroids cortisone and prednisone. People who have had an organ transplant usually take the antirejection drug cyclosporine, which is produced by the fungus *Tolypocladium inflatum* (= *Cordyceps subsellis*). The cholesterol lowering drugs, the statins, are all produced by various mold fungi. The pharmaceutical industry is constantly searching for new antibiotics and drugs to counteract microbes that become resistant to frequently used medications. Many fungi, such as *Lentinula edodes* (shiitake), *Grifola frondosa* (maitake), *Ganoderma lucidum* (ling-zhi), and *Ophiocordyceps sinensis* (caterpillar fungus), are used in Oriental herbal medicine to cure a wide variety of illnesses and to boost the immune system. Western medicine is just starting to examine these eastern remedies and finding that they probably do really work.

Wine and Beer Making

Yeasts, especially *Saccharomyces cerevisiae*, have played an important role in the development of human culture. Since

brewing is an ancient art going back for millennia, yeasts have been our allies for many years. Virtually anything that contains simple sugars is fermentable by yeasts. In wine making, the grapes are pressed and yeast is added. Fermentation breaks the sugars down into carbon dioxide and ethyl alcohol. Since barley is the main carbohydrate source in beer making, there is an added step before fermentation, that of allowing the barley to germinate to produce sugar from its starch. Various other ingredients, such as hops, oatmeal, and flavorings, are added to make the wide variety of beers that are available. The aging process in alcoholic beverages also adds to their distinct flavors.

Bread Baking

Bread making also uses *Saccharomyces cerevisiae* to ferment sugars into carbon dioxide and ethyl alcohol. However, bakers are only interested in the carbon dioxide, which makes the bread rise. The alcohol evaporates rapidly on baking.

Ethanol Production for Fuel

Saccharomyces cerevisiae, the alcohol and carbon dioxide-making fungus used to brew beer and to make bread rise, can also be used to make fuel from simple carbohydrates. In the United States, about 10% of fuel is ethanol, while in Brazil, that number is close to 25%. Unlike petroleum, bioethanol is considered to be a renewable resource. The major problem with further success in the United States is that the use of corn as the substrate has led to an increase in the price of food made from corn. It would be more ideal to use cellulosic waste, such as that from sugar cane, corn cobs and stems, wheat and rice straw, or even wood. The major problem is that *S. cerevisiae* cannot ferment cellulose, and no one has yet found an organism that can do so on an industrial scale. Most of the technology development now focuses on using fungal enzymes to break down cellulose into simple carbohydrates that can be fermented by *Saccharomyces*.

Fermentation Products for Food Use

Fungi are often used in the large-scale fermentation of liquid or solid substrates. Fermentation vats can sometimes be several hundred thousand liters in size. For example, citric acid in cola drinks is produced by large-scale vat fermentation of the deuteromycete *Aspergillus niger*. Yeasts are sometimes grown in large fermenters and used directly as food supplements. Vitamin B₂ (riboflavin) in enriched flour is produced by the ascomycete *Ashbya gossypii*. Authentic soy sauce is fermented in a three-step process with the fungi *Aspergillus oryzae* and *Zygosaccharomyces rouxii*, as well as the bacterium *Pediococcus halophilus*. Tempeh, a soybean product popular in Indonesia, is partially fermented with a species of *Rhizopus*. Many good cheeses, such as blue cheese, camembert, and brie, are ripened through the action of fungi to obtain their distinctive flavors. Blue cheeses such as Roquefort, Gorgonzola, and Stilton are ripened by *Penicillium roquefortii* – the blue color is caused by sporulation of the fungus! The white crust on the outside of brie and camembert is the mycelium of *Penicillium*

camembertii. Fungi are also essential for chocolate: the naturally bitter cocoa beans are processed into a sweet tasty candy by a "fermentation" (sensu food-scientists) using *Candida krusei* and *Geotrichum*.

Biopulping and Bioremediation

Several important industrial process, which have the potential to be great boons to ecosystem health, are in the pilot stage: biopulping and bioremediation. The lignin-degrading enzyme system of *Phanerochaete chrysosporium* is special for these two uses. One of the biggest energy and pollution expenditures in paper making comes from removal of the brown lignin from wood so that the white cellulose is all that is left to make paper. What if paper companies could use the enzymes of a fungus to remove the lignin? This could result in a savings in both energy and time and avoid the polluting wastes that are commonly dumped out of the mills. This process is known as biopulping. There are several products in the pilot stage, but no large-scale biopulping is yet being done.

To understand this system, you must know that wood consists primarily of cellulose, which is white, and lignin, which is brown. Members of *Phanerochaete* and other genera cause a white rot of wood. That is, the fungus decays the lignin and leaves the cellulose behind. There are also fungi that cause a brown rot, digesting the cellulose and leaving the lignin behind. Many kinds of fungi cause a white rot, but *P. chrysosporium* has several features that might make it very useful. First of all, unlike some white rotters, it leaves the cellulose of the wood virtually untouched. Second, it has a high optimum temperature (about 40 °C), which means it can grow on wood chips in compost piles, which attain a high temperature. These characteristics point to some possible roles for this fungus in biotechnology applications. The basis for all of *Phanerochaete's* powers come from its enzymes that can degrade lignin. This same enzyme system can also degrade chemicals that are chemically similar to lignin.

Some of the lignin-degrading enzymes of *P. chrysosporium* will also degrade toxic wastes, such as PCBs (polychlorinated biphenyls), PCPs (phencyclidines), TNT (trinitrotoluene), and similar chemicals. The structure of these chemicals is similar to that of lignin, and the ligninase enzymes will work on them. The fungus performs well on the laboratory bench, but as with many industrial bioprocesses, there are difficulties in scaling up the process. Nonetheless, this procedure has the potential to clean up some industrial and toxic waste sites.

In my lab, Adam Gusse, Paul Miller and Volk (2006) published a paper on the biodegradation of phenolic resin plastics with *Phanerochaete chrysosporium*. We demonstrated the ability of this white-rot fungus to degrade phenolic resin, a previously nonbiodegradable industrial polymer (plastic-like) that is not commercially recycled. These phenolic resin polymers, first known as Bakelite, are found gluing layers of plywood together, providing the binding matrix to particleboard, or laminating the surface of Formica™ counter tops. They are also used in constructing rotary telephone casings, bowling balls, toilet seats, motor casings, and many other everyday products. The annual production of phenolic resin is 2.2 million tons per year. Formerly considered to be non-biodegradable and contributing greatly to landfills, our work

has demonstrated, through three lines of independent evidence, that phenolic resin polymers can be degraded by *Phanerochaete chrysosporium*. (See TomVolkFungi.net for further information.)

Threatened or Endangered Fungi

Like the proverbial canary in the coal mine, fungi may be the first indicators of things going wrong in ecosystems. Remember that fungi are the threads that tie the whole food web together, since they are the primary decomposers and aid most plants as mycorrhizae in the absorption of minerals and water. Thus if something goes wrong with the fungi – if they disappear – there may be dire consequences for any plants and animals that are dependent on them. Lichens have already been proven to be accurate indicators of air quality, in both their quantity and diversity.

Several European countries maintain "red lists" of threatened or endangered fungi. One fungus that may be a candidate for the endangered species list in the United States is *Bridgeoporus nobilissimus*, a polypore fungus with a very large, perennial fruiting body (Figure 20). For a long time this fungus was in the *Guinness Book of World Records* as the largest known fruiting body of a fungus, at over 160 kg (300 pounds)! There are just eight known sites in Oregon, Washington, and California at which *B. nobilissimus* is now known to occur. It is considered by many to be a rare and probably endangered fungus. The main reason for this designation is that it is restricted to very large specimens of noble fir (*Abies procera*) and occasionally Pacific silver fir (*Abies amabilis*) with a diameter at breast height (dbh) of 1–2 m. Trees of this diameter are not very common. This fungus is considered endangered because its habitat is endangered. Unfortunately, it is not clear whether the U.S. Endangered Species Act applies to fungi. In this zoocentric world, most people are more interested in the "charismatic megafauna" than in some "lowly" fungus. However, the fungi have many important roles to play in the ecosystem and should not be ignored. No ecosystem could exist for long without fungi!

Figure 20 The author with *Bridgeoporus nobilissimus* on a large host tree of *Abies procera* (noble fir).

Two states have thus far recognized the importance of fungi by naming a state mushroom. Minnesota was the first, naming the morel (*Morchella* species) as their state mushroom. Some 10 years later, Oregon declared the Pacific golden chanterelle (*Cantharellus formosus*) as their state mushroom. Surprisingly, some forests can yield more income annually from wild mushroom harvesting than from lumber harvesting. Moreover, intact forests continue to produce edible mushrooms yearly, whereas lumber harvesting can occur only once every 50 years or so. Mushrooms for human food is only one of the many contributions that fungi make to our lives, for their fundamental decomposer role supports almost all ecosystems and so helps to provide the essential ecological services that we take for granted, as well as the recreational opportunities of enjoying nature. Fungi have contributed a great deal to our standard of living by making most of the living world possible.

Marine Symbioses: Metazoans and Microbes

Elisha M Wood-Charlson, University of Hawaii at Manoa, Honolulu, HI, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Clade Group of organisms with a common ancestor; not a taxonomic identification.

Co-evolution Mutual evolutionary influence as the result of organisms being involved in symbiosis.

Commensalism A type of symbiosis; symbiont obtains benefit with no impact on the host.

Holobiont Collective term that includes all organisms engaged in a symbiotic relationship.

Kleptoplastic The ability to harvest chloroplasts from algae; used by the secondary host to make photosynthetic products.

Mutualism Type of symbiosis; host and symbiont benefit from the association.

Parasitism Type of symbiosis; symbiont obtains benefit at the expense of the host.

Primary mutualism The initial association between a symbiont and a host.

Secondary mutualism The incorporation of a primary mutualism into a secondary host; the primary host either becomes the symbiont or is lost.

Symbiosis Intimate, protracted relationship between two or more dissimilar organisms.

The scope of biodiversity covered in this volume hints at the complexity of life on our planet. However, no organism exists in isolation, and the evolution of organisms must be considered in the context of their interactions with each other. Symbiotic associations are intimate interactions involving two or more organisms that live in a close, protracted relationship. These intimate interactions are a strong driver for the evolution of the organisms involved in the association. Although *symbiosis* can be used to describe many diverse interactions between a variety of organisms in almost every environment on Earth, this article focuses on the diversity of mutualistic partnerships involving metazoans and microbes in the marine environment. Mutualisms can be found in every marine ecosystem across the globe: from the coast to the open ocean and from the surface waters to the deep sea (Figure 1). These associations have influenced the evolution and diversification of most, if not all, extant marine organisms. In fact, several marine ecosystems, such as coral reefs and hydrothermal vents, are only possible because of mutualistic symbioses between metazoans and microbes.

Introduction

The study of symbiosis in nature began in the late 1600s with the first observation of microorganisms by Antonie van Leeuwenhoek (1632–1723). The term *symbiosis*, derived from the Greek for “living together,” was proposed 200 years later by Heinrich Anton de Bary (1831–1888) to describe phenomena such as mutualism and parasitism. However, the defined outcome of the relationship (positive or negative, depending on the perspective of the host) may become blurry as environmental conditions change (reviewed in Karst *et al.*, 2008; Sachs and Simms, 2006; Thrall *et al.*, 2007). This becomes an important consideration for many mutualisms in the coastal surface oceans where anthropogenic impacts such as eutrophication and increased sea surface temperatures are the most pronounced.

Structure in Symbiosis

Symbiotic associations come in a variety of forms and functions. The structural characteristics that form the relationship can be described in several categories: the relative location of partners to each other, how associations are transmitted between generations, and the obligacy and specificity of the relationship. These structural characteristics can be used to summarize any symbiotic association regardless of where the mutualism occurs or the overall function of the partnership.

Location is usually described as the position of the smaller “symbiont” in relation to the larger “host” (Figure 2(a)). Ectosymbionts (from *ecto*, the Greek for “out”) occur on the surface of the host, whereas *endosymbionts* (from *endo*, the Greek for “within”) occur internally, either within a body cavity but outside the cells (extracellular) or within cells (intracellular). Because of the intimate and protracted nature of mutualistic symbioses, by definition they must be maintained across generations, either through a closed/vertical or an open/horizontal transmission of symbionts to a new host (Figure 2(b)). In vertical transmission, hosts directly supply their offspring with symbionts – for example, by packaging them into egg cells – which ensures that all offspring inherit symbionts. If this is the only mechanism operating, then the system is closed to partner exchange and the association diverges together over time, resulting in coevolution of the host and symbiont lineages. In horizontal transmission, hosts produce nonsymbiotic offspring that must acquire symbionts from environmental sources. For these less intimate mutualisms, coevolution between partners typically breaks down because of the potential for partner exchange through environmental acquisition. However, the interaction between host and symbiont still drives their evolution. For example, extracellular, horizontally transmitted associations may not demonstrate coevolution, but the association still results in the evolution of specialized cells or tissues in the host that serve as accommodation for their symbionts. These evolutionary changes are not found in nonsymbiotic hosts.

Figure 1 Distribution of symbioses. (a) Global distribution of photosynthetic symbioses (sun, between 30° N and 30° S) and confirmed locations of vent sites with chemosynthetic symbioses (star). (b) Example distribution of photosynthetic (sun), chemosynthetic (star), light-producing (light-bulb), and protective (shield) associations in discrete regions of the ocean. Map courtesy of S Soares (Oceanography Department, University of Hawai'i at Manoa).

Figure 2 Structure of symbiosis. (a) Relative position of symbionts (brown circles) to host cells (orange ovals with black nuclei). (b) Transmission of symbionts from host parent to offspring.

In many cases, the mode of transmission may indicate the necessity of the interaction, especially for partnerships with vertical symbiont transmission. However, necessity may not be a two-way street; one may be an obligate partner, requiring the association for survival, and the other may be facultative, with individuals able to live with or without the association. One final layer of complexity to consider when describing a symbiotic association is the specificity between partners. Does the association occur between two partners defined at the species, clade, or subclade level, or does it lie under some higher level of classification? Can one partner be found in association with several potential partners, either occurring in a range of hosts or as hosting a range of symbionts? Marine symbiotic associations occur in a variety of structural forms, with different combinations achieving the same symbiotic function.

Functions of Symbiosis

The diversity of marine symbioses can be categorized according to the function provided to the host by the symbiont. For example, imagine hosting small plants that live inside your skin and feed carbohydrates directly to your body. Or how about a small compartment just under your skin that glows in the dark because it houses light-producing bacteria? This article describes marine mutualisms grouped by three main functions: nutrient exchange, production of light, and production of protective compounds. Nutrient-exchange symbioses bring together organisms with complementary metabolic capabilities. Light-production symbioses typically occur in the deep, dark oceans of the world or in association with nighttime activities in which they provide hosts with a mechanism for capturing prey, avoiding predators, or communicating. Symbioses that produce protective compounds function to deter grazers, competitors, predators, or pathogenic microbes.

Humans also host numerous microbial symbionts known to function in nutrient exchange and the production of

protective compounds (Turnbaugh *et al.*, 2007), so it is important to remember that metazoans utilize symbiotic associations as a way to expand our physiological and metabolic capabilities. In general, metazoans are quite limited in their capacity to process or obtain nutrients, and they rely on the diverse metabolisms of microbes to supplement their native capabilities. The symbioses discussed in this article highlight some of those traits and describe how microbes have been co-opted to function in metazoan hosts, creating a unique niche for both organisms in the marine environment.

Nutrient-Exchange Mutualisms

Photosynthetic Symbioses

The phenomenon of photosynthesis evolved once, originating in cyanobacteria (Cavalier-Smith, 2006). Today, a significant amount of global photosynthesis is still performed by cyanobacteria in the oceans, with land plants and algae contributing to the rest of the photosynthesis on this planet. If photosynthesis evolved only once in cyanobacteria, where did plant and algal chloroplasts originate? In 1905, Constantin Mereschkowsky first presented the concept that chloroplasts are derived from an ancient endosymbiotic event that combined cyanobacteria with a eukaryotic host (translated in Martin and Kowallik, 1999). This theory was later strengthened and expanded by Lynn Margulis in 1967 (as L. Sagan), with her presentation of cytological, biochemical, and paleontological evidence for a generalized symbiosis theory (Sagan, 1967) and by the discovery that chloroplasts contain DNA related to cyanobacteria (Bonen and Doolittle, 1975; Ris and Plaut, 1962; Zablén *et al.*, 1975). Aside from land plants and lichens (fungi in association with photosymbionts), all multicellular organisms with photosynthetic symbionts are found in aquatic environments.

The marine environment contains a variety of “photosynthetic animals,” or metazoans in association with photosynthetic microbes such as cyanobacteria. However, most of the photosynthetic animal hosts in the marine environment are actually secondary mutualisms – situations in which a primary mutualism such as a eukaryotic alga containing chloroplast organelles is incorporated into a secondary host. These secondarily photosynthetic associations are often found thriving under low nutrient conditions that typically limit food abundance (Johnson, 2011; Vaughn *et al.*, 2010). The photosynthetic symbiont uses sunlight to fix carbon dioxide (CO₂) into organic carbon, much of which is directly translocated to the host to supplement feeding. In return, the host provides a stable, high light environment with a constant supply of CO₂ and nutrients such as nitrogen and phosphorus. Several host examples highlighted in this article are cnidarians, such as corals and anemones, bivalves like the giant clam, and the sea slug (*Elysia* spp.), which has a unique kleptoplastic nature (Figure 3).

Cnidarians have a relatively simple body plan comprised of two cell layers: an outer epidermis, which is a central acellular lay of mesoglea, and an inner gastrodermis that lines the digestive cavity and houses the intracellular endosymbionts (Figure 3(a)). Symbiont transmission between generations

can be vertical or horizontal, depending on the host species. Hosts that employ vertical transmission typically transmit symbionts in egg cells that become fertilized to produce offspring or, in the case of brooding species, may transfer symbionts to offspring while they are still within the parent colony (Figure 2(b)). Horizontal transmission is established through feeding: the host’s gastrodermal cells phagocytose the symbionts, and the symbionts survive by resisting digestion through mechanisms not yet understood. For reef-building corals, the symbiosis is considered obligate. However, some hosts, such as the sea anemone *Aiptasia* (Figure 3(b)), and some strains of the symbiotic algae, can be found free-living. Regardless of lifestyle, symbiotic cnidarians are only found in association with dinoflagellates in the genus *Symbiodinium*, which is described later in this section.

Corals (animal host and algal symbiont) living in warm, shallow waters have a unique role in the marine environment. They create the biological and structural foundation for the most diverse marine ecosystem on the planet: coral reefs. The reef structure is built by coral polyps, clonal individuals resembling anemones, that deposit a thin layer of calcium carbonate, layer by layer, generation after generation, for decades or even centuries (Figure 3(c)). Since corals typically live in low-nutrient waters, the nutritional supplement provided by their photosynthetic symbionts significantly enhances calcification and therefore growth of the colony. The coral structure provides habitat for many of the diverse organisms that live on coral reefs. Some corals with branching morphology show rapid growth, laying down 10–20 cm of skeleton per year, whereas corals with a more uniform, massive structure are estimated to add only 0.5–1 cm of growth per year (Figure 3(d)). Reef building is a dynamic process. Even as corals build the reef, wave motion and biological perturbation continuously degrade it. The reefs we are familiar with today have been around for thousands of years; however, changing environmental conditions on a global scale (increasing sea surface temperatures and ocean acidification) and on local scales (sedimentation and eutrophication from coastal runoff) are undermining the corals efforts to maintain the structure of the reef, and these important yet fragile ecosystems may eventually be lost in many places around the globe.

Giant clams are the largest bivalves in the world, reaching up to 120 cm in length and weighing more than 200 kg (Figure 3(e)). They are found in association with coral reefs in the South Pacific and Indian oceans. They also host *Symbiodinium* dinoflagellates as symbionts, with symbionts being acquired by host larvae during feeding. Symbionts that successfully avoid digestion are housed extracellularly in a tubular extension of the stomach that branches out into the mantle cavity. This structure is designed to provide the symbionts with ample light for photosynthesis and also creates the unique patterns observed in the clam’s mantle tissue. For the clam, this is an obligate association, with up to 95% of the photosynthetically fixed carbon being translocated to meet the host’s metabolic requirements.

Symbiodinium, the genus of dinoflagellate symbionts found in cnidarians and giant clams, was originally thought to be a single species, *Symbiodinium microadriaticum* Freudenthal (Freudenthal, 1962). Advances in genetic techniques have revealed at least nine different lineages within *Symbiodinium*

Figure 3 Photosynthetic symbioses. (a) Cross-section of a cnidarian tentacle depicting the tissue layers and location of symbionts (orange circles). (b) *Aiptasia pallida* in symbiosis with *Symbiodinium* (top) or aposymbiotic (bottom). (c) Deposition of calcium carbonate layers by coral polyps builds the reef structure. so far (Figure 3(f)). Although the taxonomy of the symbiont has not been fully resolved, host specificity within *Symbiodinium* can range from highly specific (associating with single subclade of *Symbiodinium* through time and space and between generations) to relatively flexible. For example, the giant clam associations appear to be relatively flexible, harboring heterogeneous populations of *Symbiodinium* in a single host. Outside of these metazoan associations, *Symbiodinium* is also found in symbiosis with single-celled protists such as foraminiferans.

Green sea slugs are one of the more bizarre examples of a nutrient-exchange symbiosis creating a photosynthetic animal. This association has a different interpretation of an animal-algal mutualism because the host sea slug steals chloroplasts from the algae, a process also known as *kleptoplasty*. The green sea slug feeds on algae, but instead of acting as a secondary host to the algal-chloroplast association, the sea slug bypasses the primary host by harvesting the chloroplasts directly from the algal cells (Figure 3(g)). To maintain a functioning

chloroplastic organelle without the primary algal host, the animal genome has acquired genes, typically found in plant or algal genomes, that support photosynthetic function. The majority of studies on kleptoplasty have been conducted on sacoglossan sea slugs in the genus *Elysia*, but this phenomenon also occurs in marine ciliates and foraminifera (reviewed in Wise *et al.*, 2006). The record for kleptoplastic living is held by *Elysia chlorotica*, surviving for 10 months exclusively on plastid-generated photosynthetic products (Rumpho *et al.*, 2011).

Chemosynthetic Symbioses

Although most of Earth's environments are supported by photosynthetic activity, several unique systems rely on chemosynthesis to fix carbon. Like the process of photosynthetic light harvesting, the oxidation of reduced sulfur and methane also releases high-energy electrons that can be converted to cellular energy and used to fix CO₂ into organic compounds. The most familiar chemosynthetic habitats, the hydrothermal vent systems, are found in the deep sea, but chemosynthetic symbioses are present at a range of depths and across many ocean environments (Figure 1). The more we look, the more chemosynthetic diversity is discovered in terms of habitat (vent, cold seeps, etc.), metabolic pathways, and symbiont–host partnerships (for a comprehensive review see Dubilier *et al.*, 2008). As with coral reefs, the deep ocean chemosynthetic symbioses provide the foundation, the source of fixed organic carbon, for the entire vent ecosystem. To highlight nutrient-exchange symbioses characterized by chemosynthetically fixed carbon, the author will focus on the classic hydrothermal vent tubeworms and bivalves (Figure 4).

Hydrothermal Vents

Formations of hydrothermal vents occur above pockets of magma under the seafloor, usually along tectonically active oceanic ridges like the East Pacific Rise and the Mid-Atlantic Ridge. Cold seawater seeps in through the surrounding seafloor, where the pocket of magma heats the water causing it to react with surrounding rocks, changing the chemistry of the water until it becomes highly acidic and rich in sulfides and other reduced metals. The heated water rises back to the seafloor and is released through vent sites at temperatures up to 400° C.

Biological communities were discovered along hydrothermal vents during the exploration of the Galapagos rift (1977–1979) (Karl *et al.*, 1980). Compared to other regions of the deep ocean, the vent community contained substantially more biomass than expected, since photosynthesis is not a significant source of organic carbon to the deep ocean. Originally, these communities were thought to be supported by free-living chemosynthetic bacteria, but further analyses revealed that mutualistic associations between animal hosts, such as giant tubeworms and bivalves, like clams and mussels, and chemosynthetic bacterial symbionts were responsible for generating the organic carbon that supports these vent communities.

Riftia vent tubeworms were the first animals found to host chemosynthetic bacteria (Cavanaugh *et al.*, 1981), and in spite

of the challenges of studying organisms that live miles below the surface of the ocean, significant progress has been made in understanding these interactions. Sulfur-oxidizing bacterial symbionts are intracellular within the trophosome, a highly vascularized symbiosis organ inside the *Riftia* tubeworm. The symbionts provide chemosynthetically fixed carbon to the host, and the host provides the symbionts with the necessary substrates: sulfides and oxygen (O₂) from the environment and CO₂ from host respiration. Symbiont transmission between generations is horizontal, as host larvae are symbiont-free and acquire symbionts from the environment. As the larvae develop, their digestive structures are lost. Adult tubeworms have no digestive system, being entirely dependent on their symbionts for nutritional support. The *Riftia* tubeworms host a specific subclade of γ -proteobacteria, a large group of bacteria that contain free-living and pathogenic strains, as well as symbionts found in many other marine symbioses (Thornhill *et al.*, 2008).

One of the most interesting features of this association is the modified physiology of the host (Stewart and Cavanaugh, 2006). For example, the host must supply sulfides and O₂ to the trophosome. The transport of O₂ in the blood of the host is performed by hemoglobins, which are easily poisoned by sulfides that compete with O₂ for binding sites on the protein. In addition, reduced metals begin to react with dissolved O₂ immediately on release from the vent, oxidizing the metals and decreasing their energetic yield for chemosynthesis. To solve these problems, the host tubeworm grows at the interface between the sulfide-rich vent flow and the surrounding O₂-rich seawater, allowing access to both resources. To eliminate the toxicity of sulfides in the blood, the host tubeworm has developed a modified hemoglobin structure adapted to reversibly bind sulfide (for release in the trophosomes), independent of binding O₂ for host respiration.

Clams and mussels (bivalves) are found farther from the vent water source and typically house their symbionts in or on gill tissue, depending on the species (Dubitier *et al.*, 2008). The symbionts are again represented by a unique subclade of γ -proteobacteria, although symbiont transmission depends

on the association. Vesicomylid clam symbioses show cospeciation between host and symbiont, which is reflected in their symbiotic form: an intracellular, vertically transmitted association in which the symbiont is carried within the eggs. For other bivalve partnerships, less is known about their modes of transmission; however, there is no clear cospeciation, implying horizontal or mixed modes of transmission.

As for *Riftia* tubeworms, the bivalve host must supply their symbionts with the materials necessary for chemosynthesis and therefore face the same problems. Harboring the symbionts on the gill tissue provides an adequate supply of O₂ and CO₂ to the symbionts, but the concentration of reduced metals in the seawater decreases with distance from the source. In response, bivalves have developed several mechanisms for concentrating sulfides. For example, clams can extend their foot deep into sulfide-rich vent cracks that fissure out from the main vent site, so O₂ and sulfide acquisition is spatially separated. Another mechanism for concentrating reduced metals is the temporal separation of substrate acquisition. Some bivalves move up and down in the sediment. They collect O₂ from the sediment–seawater interface and then burrow deep into the sediment where sulfides are enriched. As a mechanism to deal with sulfide toxicity in the circulatory system, the host has developed a separate carrier protein that binds sulfides, leaving hemoglobin to carry O₂.

Vent sites are patchy in space and time, occurring where and when tectonic conditions are appropriate. Once they occur, they are ephemeral, typically lasting on the scale of years to decades. Therefore, establishment and community production at vent sites occurs rapidly, reaching maturity within a few years. Mature communities produce a vast amount of motile larvae that move along the ocean currents in search of new vent sites.

Nutrient Conversion

Not all nutrient-exchange symbioses involve autotrophic symbionts. The diverse capacity of microbial metabolism has resulted in symbiotic associations with varied functional roles, including the conversion of complex carbon compounds and the fixation of atmospheric nitrogen into forms that can be used by the host. Many symbioses, especially those occurring in nutrient poor regions of the ocean where nitrogen is limiting, such as cnidarian–algal mutualisms (see Photosynthetic Symbioses) have secondary associations with nitrogen-fixing microbes, typically marine cyanobacteria. The fixation of atmospheric nitrogen is covered in depth elsewhere in this volume and a recent review by Fiore *et al.* (2010) highlights nitrogen fixation in marine symbioses, including interesting associations between cyanobacteria and diatoms. Instead this section highlights two marine symbioses involved in the conversion of complex carbon compounds. The first association is unique within the field of symbioses as a whole and so far found nowhere else but in the oceans; the second is very common on land but unique in the marine environment.

Worms and Whales

The death and sinking of a large marine vertebrate, such as a whale, delivers a rich carbon source to the deep ocean, where

large scavengers such as sharks, crabs, and fish recycle the majority of the fallen biomass into living tissue. However, when only the bones remain, a unique marine microbial symbiosis is there to break them down.

During an exploration of the ocean floor in Monterey Bay, California, in 2002, the bones of a gray whale were found covered in red feathery plumes of worms later determined to be a new genus named *Osedax* (Latin *bone devourer*) (Rouse *et al.*, 2004) (Figure 5). Like their hydrothermal vent relatives, the adult worms have no mouth or digestive system, and the larvae appear to be without symbionts, so the association is likely horizontally transmitted. Their symbionts are also γ -proteobacteria; however, members of this unique *Osedax*-associated subgroup of γ -proteobacteria are heterotrophic. They utilize the lipid-rich hydrocarbons inside the bone marrow as a carbon source for their host, making this nutrient-exchange association unique in the world of symbiosis. Also, like their vent counterparts, this symbiosis relies on ephemeral nutrient sources, so they establish quickly, occur in large populations, and reproduce in vast numbers. Since their original discovery, 17 species of *Osedax* worms have been identified throughout the world's oceans.

“Worms” and Ships

Although these organisms are called *shipworms*, or “termites of the sea,” they are actually bivalve mollusks that bore into and consume wood submerged in the ocean. Historically, they have caused extensive damage to human-made structures, including the demise of several ships during Christopher Columbus’s fourth voyage (early 1500s), and they continue to feed on the wooden bridges and piers in coastal cities today. Like termites on land, shipworms subsist on wood, which is very nitrogen-poor and difficult to digest, so the host, once again, relies on γ -proteobacterial symbionts to convert nutrients into a form usable by metazoans (Luyten *et al.*, 2006). Shipworms host a consortium of intracellular, endosymbiotic cellulose-digesting, nitrogen-fixing microbes.

Production of Light

Bioluminescence, the endogenous production of light through biological activity, involves a chemical reaction in which the oxidation of luciferin (substrate) by luciferase and a photo-protein (enzyme) produces oxyluciferin and light (products) (Figure 6(a)). Bioluminescence is relatively rare on land and found in arthropods such as fireflies, a snail, a few earthworms, and some fungi. Bioluminescence in the marine environment, however, is quite common and found in a diverse array of organisms ranging from bacteria to fishes; it is especially common in nocturnal creatures or those living in the deep ocean where little sunlight penetrates (reviewed in Haddock *et al.*, 2010). The luminescence reaction in the marine environment produces light in the blue-green spectrum (~ 470 nm), probably because blue light transmits the farthest in water. One easy-to-see example sometimes occurs at

night along the coast and appears as waves that glow as they break on the shore. This light is produced by dinoflagellates during bloom events (Figure 6(b)).

Although many marine organisms produce their own light, others have become hosts to light-producing marine microbes. For example, many squid and bony fish harbor packets of luminescent bacteria that glow within the body of the animal. These light-producing symbioses appear to have several independent origins – hosting different species of luminescent bacteria in different locations around the host and for different purposes such as communication, prey attraction, and camouflage. The hosts in these associations are highly specific for their luminescent symbionts even though the associations are extracellular and most if not all are horizontally transmitted. The bacterial symbionts and their luminescent free-living relatives are members of the γ -proteobacteria. Symbiotic strains include at least one cultured species in the genus *Vibrio*

(*V. fischeri*) (Figure 6(c)) and several species of *Photobacterium* (*P. leiognathi* and *P. phosphoreum*). The necessity of the association for host survival is less well defined than the nutrient-exchange symbioses. However, hosts lacking the ability to produce light for prey attraction or predator avoidance will likely not be successful over time. From a symbiont perspective, the culturable strains are considered facultative and free-living under nutrient-rich conditions, but several strains remain resistant to culturing, suggesting that they are highly specialized for survival inside the host light organ. However, most bacterial species are currently unculturable, so this feature does not guarantee that they are in an obligate association with their host. As a mutualism, the hosts gain a variety of functions that will be highlighted shortly, and the bacteria are provided with a nutrient-enriched environment for growth, allowing populations to survive in much greater densities than in the open ocean.

Density becomes an important consideration for light production by bacteria, since a bacterium is only several microns long. The amount of light produced by a single cell quickly becomes a waste of valuable energetic resources. However, when enough cells are present in a small area such as a host's light organ, the light output becomes substantial. But how do bacteria know when enough cells are present? The regulation of light production includes a mechanism for *quorum sensing*, allowing the cells to chemically detect density (also important in pathogenesis). Quorum sensing involves the continual release of a chemical into the environment. When the chemical, an autoinducer, reaches a critical concentration, it triggers the induction of a metabolic process. In the case of light production, the autoinducer turns on the production of the luciferase enzyme, thereby turning on luminescence (Figure 6(d)).

Fish

Light production in bony fish is often autogenic, but those that host bacterial symbionts have developed a variety of symbiosis structures (Haygood, 1993). Several of these host organs occur as outpockets of the gut, which suggests that colonization occurs during feeding from free-living populations (confirmed by culturing). Others house the bacteria in highly specialized superficial structures that are open to the environment. However, their symbionts have not been seen free-living (nor cultured), so colonization mechanisms are unknown. The location of the light organ and direction of light emission provides some information about function, with a few representative examples described in the following paragraphs.

Ponyfish, or Leiognathids, reside in shallower, near-shore waters in the Indo-Pacific Ocean and are characterized by a protrusible mouth and a circumesophageal light organ (Figure 6(e)). The light organ is colonized by *P. leiognathi*, and emission of light by the light organ is controlled by highly modified structures in the host fish. The light organ is positioned next to the gas bladder, with a dorsal shutter that controls the entrance of light into the gas bladder. The gas bladder is silvered over to allow the light to be reflected to the posterior end and out through the ventral side of the fish body

near a transparent anal fin (Mcfall-Ngai and Dunlap, 1984). Other lateral shutters are present around the light organ to control lateral light emission. The position of light emission appears to correlate with function; ventral emission near the anal fin acts as camouflage, and lateral emission plays a role in communication.

Anglerfish or Ceratioids, occur in the deep, dark abyssal ocean as solitary, relatively rare fishes. They are characterized by a prominent bioluminescent lure at the end of a modified dorsal spine that extends out over the head (Figure 6(f)). The superficial light organ is colonized by a strain of unculturable *Vibrio*-like species of symbiont. The function of the lure, easily identified by the location, is used for prey attraction. Symbiont transmission is unknown, but the rarity and solidarity of these fishes and the fact that their symbiont has not been cultured suggest a mechanism for vertical transmission.

These few examples highlight the major functions of luminescence in marine fishes but are not the only examples. Similar phenomena are seen in more than 20 families of bony fishes and are present in all marine environments around the globe.

Squid

Bioluminescence is very common in squids, with at least 70 luminous genera. Most produce endogenous light, but only a few families are known to utilize bioluminescent bacteria: the *Sepiolidae* and *Loliginidae*. One species, *Euprymna scolopes*, the Hawaiian bobtail squid, has become the model organism for studying light-producing symbioses, as well as a model for host symbiont-pathogen interactions and metazoan immunity in general (Mcfall-Ngai, 2008; Mcfall-Ngai *et al.*, 2010). This particular association has become a well-studied scientific model because the organisms are easy to catch in the wild, the host can be reared from egg to adult in aquaria, and the *V. fischeri* symbionts can be cultured independently of the host (Figure 6(c)).

Hawaiian bobtail squid are small, nocturnal creatures, about 4 cm in length, that burrow in the sand during the day and come out at night to hunt. The light organ lies ventral to the ink sac, which reflects light emitting from the light organ. This reflected light creates down-welling, counter illumination that masks any shadow caused by overhead moon or starlight. The light organ consists of two enclosed sacs called *crypts* which are connected to the surrounding seawater through ducts that open up as pores in the mantle cavity (Figure 6(g)). In spite of the continuous connection with the environment, the light organ houses a dense monoculture of *V. fischeri*, which are acquired from the environment by juvenile squids, typically within hours after hatching. Adults regulate symbiont population by venting up to 95% of their symbionts into the environment at the end of every night. Then they bury themselves in the sand for the day, allowing the bacterial culture to repopulate; by nightfall, the light organ is back to full capacity.

The initiation, recognition, and establishment stages of this symbiosis are very well understood. They are presented in some depth here to illustrate the intricate regulation mechanisms involved in setting up a highly specific, horizontally transmitted symbiosis (Nyholm and Mcfall-Ngai, 2004). Most

if not all horizontally transmitted associations likely require several selection stages as well, but for most associations the mechanisms remain unknown.

Initiation begins at contact between potential partners. Typically, there is an initial mechanism of recognition that allows for the two partners to remain in contact, especially in the marine environment where water motion can easily disrupt the interaction. In the *Euprymna-Vibrio* association, juvenile squid ventilate water into the mantle cavity, drawing in the surrounding microbial community. The presence of bacteria in the seawater induces the host to generate mucus on specialized colonization appendages near the ducts to the light organ. Even though any bacteria can induce mucus shedding, only some (the Gram-negative bacteria) are capable of adhering to the mucus; out of those that can attach, *V. fischeri* is preferentially recruited, even though it only represents <0.1% of the population. This is the first stage of the “winnowing” process (Nyholm and Mcfall-Ngai, 2004).

Recognition continues as potential symbionts migrate toward the pores and down the ducts to the light organ. The environment within the ducts is highly discriminatory, and only *V. fischeri* is able to reach the crypts for colonization.

Establishment within the crypts of the light organs is not just a matter of getting there. Once *V. fischeri* has entered the crypt, it begins to divide and populate the chamber. However, *V. fischeri* strains that are unable to produce light are unable to maintain residence (Lupp *et al.*, 2003); therefore, the host has some mechanism of sensing light production, ensuring that its symbiont culture is doing its part. Once a culture of symbionts has been successfully established, molecular signals are sent to the host to halt mucus production in the mantle cavity, disassemble the colonization appendages near the entrance to the ducts, and resist subsequent infections. The mature symbiosis persists for the life of the squid.

Production of Protective Compounds

So far, the mutualistic marine microbes presented in this chapter have been shown to fix carbon using light or chemical energy, convert cellulose and atmospheric nitrogen into a biological usable form, and generate light. This final section introduces the production of protective compounds (which function in host defense) by microbial symbionts. Many of these protective compounds are metabolite derivatives, by-products of metabolic pathways not found in metazoans. A diverse array of marine microbes are capable of producing an assortment of unique protective compounds; as marine metazoans go, sponges are the experts at hosting microbial symbionts (reviewed in Taylor *et al.*, 2007). In fact, one facet of research on marine sponges targets the isolation of bioactive natural products from sponge symbiotic communities for use in pharmaceuticals.

Sponges

Sponges represent the base of the metazoan tree of life. They are sessile filter feeders with a relatively simple body structure, minimal coordination or differentiation of tissues, and a

Figure 7 Sponge biodiversity. Included are the yellow tube sponge (*Aplysina fistularis*), the purple vase sponge (*Niphates digitalis*), the red encrusting sponge (*Spiratrella coccinea*), and the gray rope sponge (*Callyspongia* sp.). Photo credit: reproduced from Twilight Zone Expedition Team (2007) NOAA-OE.

well-adapted innate immune system (Figure 7). Their body structure is designed to filter large volumes of water for food particles, with estimates of up to 20,000 l of water per kilogram of sponge per day (Vogel, 1977). This high-throughput lifestyle exposes the sponge to a vast array of microbes from the environment, which may end up as food, microbial mutualists, or even pathogens. Regardless, sponges continue to be very successful, representing a significant component of the benthic marine community worldwide. Sponges, as well as other sessile filter feeders such as corals, rely on the production of protective compounds as a defense mechanism against natural threats such as pathogens, parasites, predators, biofoulers, and competitors. So far, many of these compounds appear to be secondary metabolites produced by microbial symbionts, and sponges host an amazing diversity of microbes from all domains of life – Bacteria, Archaea, and Eukarya. The sponge microbial community can contribute up to half of the host’s biomass, with microbial densities 100 times greater than the surrounding seawater. The sponge holobiont is therefore capable of producing a vast array of bioactive metabolites, with several hundred new metabolites characterized each year.

With all of this sponge-associated microbial diversity, several fundamental questions arise before the system can be considered a symbiosis, such as “How different are the microbial assemblages from the surrounding environment?” and “Do the associations persist across space and time?” With recent advances in molecular biology and genetics, it seems clear that sponges do host specific microbial communities, relatives of free-living bacteria found only in sponges that seem to be relatively stable across space and time. Some symbionts are intracellular endosymbionts, whereas others are extracellular endosymbionts within the sponge body (Figure 2). Some symbionts are vertically transmitted in the egg, sperm, or brooded larvae, and others are horizontally transmitted through mechanisms that are not well understood (Webster *et al.*, 2010). The complex diversity within these associations masks a clear determination for the facultative–obligate nature of the relationships. However, from the perspective of a

mutualism, the sponge seems to act as a protective, high light (in shallow water habitats), nutrient-enriched ecosystem that harbors a complex symbiont community. In addition to producing various protective compounds, the symbionts may also participate in nutrient-exchange associations similar to those previously described such as fixing carbon via photosynthesis in high light environments and chemosynthesis near vent systems and sponge-specific strains of cyanobacteria that fix atmospheric nitrogen for hosts living under low nutrient conditions. However, as with several other mutualisms described here, many sponge communities occurring near coastal areas are under threat from changing environmental conditions.

Sponge symbioses demonstrate the elegant complexity of marine symbioses, but they also highlight the difficulties inherent in trying to study these complex associations. When considering their important role in the ecosystem and their potential benefit to the field of human medicine, it is important that science continues to explore the role of hosts and symbionts in complex partnerships. The sponge's symbiotic community also highlights the importance of considering individual organisms in the context of their association with each other.

Symbioses in the Future

The symbioses presented in this chapter not only represent the diversity of mutualisms between metazoans and microbes in the marine environment but also illustrate the range of complexity in symbiotic associations – from light production involving a single host species and a monoculture of microbial symbionts to sponge associations, where one host may associate with many symbionts of different forms and functions – with a level of microbial diversity that rivals an ecosystem. In either case, neither the host nor the symbiont can be viewed exclusively as an isolated organism. Their life histories are interconnected, interdependent, and interactive on all levels of biology, from cell to ecosystem, across evolutionary time. From a diversity perspective, each organism involved in a symbiosis should be considered as an individual and as a collective organism. If one considers parasitism and viral infection, then every organism on Earth becomes part of a collective. This is especially important when trying to understand an organism's past, present, and future evolutionary trajectory.

From creating the most diverse marine ecosystems in the ocean to potentially providing cures for disease, the importance of marine symbioses cannot be overstated. However, like much of the diversity presented in this volume, these symbioses face huge challenges in the future. The ocean is undergoing rapid change, with increases in sea surface temperature and acidification occurring on a global scale, and eutrophication and invasive species impacting local ecosystems. Although some associations may be relatively protected from these human impacts by their remote locations (e.g., hydrothermal vent communities), those that thrive in the surface oceans, such as cnidarian–algal symbioses and complex sponge communities, are under severe stress from these rapid changes. In addition to the acute impacts, these stressors also affect the physiological health of the holobiont,

making the collective more susceptible to infection and disease. For the few marine mutualisms in which the impacts of changing ocean conditions have been tested, the outcome is generally negative, causing disruption or dissolution of the symbiosis (Dubinsky and Stambler, 1996; Ove Hoegh-Guldberg, 1999; O. Hoegh-Guldberg *et al.*, 2007; Weis, 2010). However, we are still decades away from really understanding what our future oceans will look like and whether these globally important marine symbioses have the potential to adapt and survive.

Glossary

Bacteriophage A virus that infects a bacterium.

Cyanophage A virus that infects a cyanobacterium.

Lysogen A bacterium which has a temperate virus integrated into its genome. So called because it may lyse at some later time as a result of the virus excising from the genome and initiating replication (induction). This occurs spontaneously with low probability or with high probability in response to a stress to the host cell.

Lytic virus A virus for which the usual or only mode of replication is through synthesis of new virions and lysis of the host cell.

Plasmid A piece of DNA (usually circular) that can replicate independently of the chromosome of a cell and which codes for supplementary (noncore) functions.

Temperate virus A virus for which there is a high probability that the viral genome will reside passively in the host cell, sometimes by integrating its genome into the host genome, rather than initiating a lytic infection, thereby creating a lysogen or a persistent infection.

Transposon A DNA sequence that can transpose itself, or a copy of itself, from one location to another within a larger segment of DNA or from one molecule of DNA to another. Also referred to as “jumping genes.”

-virad A suffix denoting viruses that belong to an order of viruses (e.g., viruses in the order *Picornavirales* are picornavirads).

-virid A suffix denoting viruses that belong to a family (e.g., viruses belonging to the family *Phycodnaviridae* are picornavirids).

Virion An individual viral particle.

The Discovery of Viruses

The agents of viral diseases were being studied by some eminent microbiologists such as Louis Pasteur, by at least the 1880s, but the truly unique character of these infectious agents was not fully appreciated for some time. The first clue that viruses were not like other known pathogens came from experiments conducted independently in the 1890s by the Russian scientist Dmitri Ivanovsky and the Dutch scientist Martinus Beijerinck on a disease causing agent in tobacco plants in the 1890s. These scientists discovered that sap from infected plants retained its infectivity even after passage through filters with pores small enough to remove bacteria. This filtration test became the basis for assigning other pathogens to this new operationally defined class referred to as “filterable agents” (Levine and Enquist, 2007). In the subsequent 114 years, the study of viruses has not only led to a detailed understanding of their molecular nature, diversity, and ecology, it has resulted in the elucidation of some of the fundamental processes of cells in a new field of research (molecular biology), and led to relief from some of the most virulent diseases known to humankind. Some landmarks in virology at the beginning of the twentieth century included the discovery and identification of the viral agents of diseases such as yellow fever, influenza, rabies, and polio, and the realization that viruses were involved in some types of cancer. The discovery that bacteria are also susceptible to viral infections was discovered independently by Frederick Twort in 1915 and Felix d’Herelle in 1917. The first clear proof that viruses are particles and not a fluid was provided by d’Herelle’s experiments in which he showed that dilutions of the lytic agent resulted in discrete zones of lysis on a lawn of bacteria. This was later confirmed with the application of electron microscopy (1939) and X-ray crystallography (1941) to the analysis

of viruses, which provided the first detailed views of the structure of viruses. The relative simplicity of bacteriophages, and the ease with which they could be propagated in the lab under controlled conditions, made them an attractive model system for the nascent field of molecular biology. Work with bacteriophages resulted in the demonstration that nucleic acids, not proteins, were the repository for genetic information (1950s), the elucidation of the mechanisms of gene regulation and of the triplet code of genes (1960s), and the development of tools that led to recombinant DNA technology (1970s). The first genome to be sequenced was that of the RNA-containing bacteriophage, MS2, in 1976, followed by the DNA genome of bacteriophage, ϕ X174, in 1977. These were the inaugural events in the genomics revolution in biology. The number of viral genomes completely sequenced is now in the thousands and rising rapidly.

Viruses and Biodiversity

In the context of biodiversity, viruses occupy a curious position. Since they are not organisms *per se*, they might be considered exempt from the discussion. However, they are extraordinarily diverse biological entities, both genotypically and phenotypically, and have been instrumental in promoting biodiversity among all cellular life forms. Viruses are clearly distinct from the cellular life on which they depend for replication in several important respects (Lwoff, 1957) the most salient being that they replicate by assembly rather than division (Figure 1). They are, in essence, molecular symbionts of cells, but unlike other molecular symbionts, such as plasmids and transposons, they package their genome in a protein shell (capsid) for efficient dispersal outside of a cell. Encapsidation serves to protect the viral nucleic acid from degradation in the

Figure 1 Comparison of the modes of replication of cells and viruses. Cells acquire energy and material from the environment to grow in size and to increase the population by binary fission (a). Viruses neither grow nor divide, but replicate by directing the machinery of a host cell to synthesize constituent parts, which then self-assemble into new virions (b). In the mode of replication shown in (b), the viruses act as parasites (or parasitoids) and the exit of the virions from the host may or may not result in lysis of the cell. Some viruses are capable of a different mode of replication wherein the genome merges with the host genome (c). The virus genome is then replicated along with the host genome and the viral DNA is propagated into each daughter cell. Genes encoded by the integrated viral DNA can alter (or convert) the phenotype of the host. Such conversions are often advantageous for the host, and in such cases the virus-host hybrid can be viewed as a mutualism.

environment and provides the mechanism by which a virion can recognize and infect another appropriate host cell. Because of the explicitly extracellular phase in the viral replication cycle – a phase in which the virions have a proteome and a distinct morphological phenotype – viruses are often casually gathered under the umbrella term “microorganisms.” This usage, unfortunately, blurs the fundamental difference between viruses and cells, but perhaps explains why they, alone among the molecular symbionts, have a well-developed taxonomy modeled on that of other organisms.

Viruses are assigned to orders, families, genera, and species, but they are not explicitly represented in the canonical “Tree of Life,” because they do not share common ancestry with cells. Rather, different types of viruses appear to have arisen from cells in multiple, independent events over the history of life on earth (Morse, 1994). The diversity among viral genomes, which may be single- or double-stranded RNA (ssRNA or dsRNA) or DNA (ssDNA or dsDNA) depending on the virus, is

suggestive of multiple origins. This diversity in the nature of the genetic material is in stark contrast to all extant cell-based organisms. Despite the impressive morphological and metabolic diversity seen in the domains *Archaea*, *Bacteria*, and *Eukarya*, all have genomes composed of dsDNA. The term “virus,” then, does not refer to an evolutionarily coherent group, but is better seen as a convenient name for a collection of replicating, evolving, biological entities that share some distinctive features in their lifestyle. Even among the viruses, however, there is variation in the mechanism of replication and the relationship between virus and host cell.

Because some viruses kill their host cell, they are sometimes referred to as predators. Given the nature of virus–host relationships, however, they are more appropriately classified along the spectrum of symbioses that has been defined for cellular organisms (Kuris and Lafferty, 2000). In one mode of infection, viruses replicate in a cell, releasing multiple progeny at the expense of the host. In some cases, the virus kills the

host in the manner of a parasitoid (**Figure 1(b)**). In other cases, viruses are produced, but are shed from a cell without killing it, making the virus a parasite. In another mode, the viral genome merges with the genome of the host cell that it has infected (**Figure 1(c)**). By becoming part of the genome, the virus is replicated passively whenever the cell divides and each daughter cell obtains a copy of the hybrid genome. The presence of viral DNA in the genome increases the replication burden of the host. If the presence of the viral DNA provides no compensatory benefits, the integrated viral genome is a (molecular) parasite. In many cases, however, genes encoded by the integrated virus are expressed, which alters the phenotype of the host cell in ways that are beneficial. This phenomenon, which is particularly well documented in pathogenic bacteria, is known as lysogenic conversion and represents a mutualism.

In life, symbiosis is the rule rather than the exception and it seems most probable that molecular parasites and virus-like agents were present even at the earliest stages of the origin of life (Koonin, 2009). Even some viruses, known as satellite viruses, have obligate symbiotic relationships with other viruses (Krupović and Cvirkaite-Krupović, 2011). Although viruses are frequently associated with negative consequences (disease and death), there is ample evidence that they are every bit as much a creative force in the evolution of cellular life. By virtue of their obligate, intracellular, symbiotic relationships with cells, viruses serve as a mechanism by which genetic diversity is introduced to a cell's genome. Viruses may alter a cell directly via lysogenization, but they also mediate gene exchange between organisms and gene duplication within organisms, thereby providing raw material for natural selection. Remnants of viral genes litter the genomes of cells and hint at the profound contribution of viruses to the expansion of biodiversity (Villareal, 2004). Therefore, although viruses may not appear explicitly, their presence is implicit in the shape and branching patterns of the tree of life (Villareal and Witzany, 2010). In this article, viral diversity *per se* will be the focus, rather than the mechanisms by which viruses promote biodiversity in cellular organisms.

Classification of Viruses

Various classification schemes have been devised in attempts to impose some logical order on the extraordinary diversity of viruses. Earlier schemes include one in which viruses were all placed in the order *Virales* and were classified based strictly on the type of organism they infect (Holmes, 1948) or on the diseases they cause, but these criteria resulted in arbitrary and artificial distinctions and a taxonomy fundamentally at odds with evolutionary relationships. More satisfying is to distinguish viruses based on the properties of the virions themselves. One such system is that proposed by Lwoff *et al.* (1962) and referred to, accordingly, as the LHT system. A strictly sequence-based system, molecular taxonomy, was proposed as the most rational approach for classifying viruses (Lanni, 1964), but was criticized for its lack of practicality (Lwoff and Tournier, 1966), because sequencing and bioinformatics were poorly developed at the time. An alternative nucleic acid-centric system (Baltimore, 1971) classifies viruses based only

Figure 2 The Baltimore Classification scheme. Depending on the nature of a viral genome, it must go through different steps to be converted into messenger RNA (mRNA), which is required for the information to be translated by the protein-making machinery of the host cell. The nature of the genome and the conversions it goes through to result in mRNA is the basis for discriminating seven different types of viruses that are known as Baltimore Groups I–VII.

on the type of nucleic acid (DNA or RNA, single- or double-stranded) that makes up the viral genome and by the steps required to decode and replicate the genome. Regardless of nucleic acid type, all viruses need to produce mRNA that can be translated into protein. The steps by which this is achieved vary according to the nucleic acid type and, for single-stranded genomes, the sense in which the information is encoded. The modern Baltimore classification scheme distinguishes seven groups of viruses that account for these differences (**Figure 2**). This scheme is partially congruent with some of the higher order viral taxonomy as presented by the International Committee on Virus Taxonomy (ICTV), but with only seven categories it is clearly insufficient for detailed classifications. The LHT system provided finer level discrimination and, with modifications, served as the early basis for a comprehensive viral taxonomy. As sequencing has become more commonplace, molecular taxonomy as envisioned by Lanni has become the accepted basis for delineating taxonomic groups at the finest level. In this article the presentation of viral types is organized according to Baltimore Group, followed by the ICTV-approved orders, families, and genera.

The Scope of Virion Phenotypic Diversity

The collection of biological entities referred to as viruses is defined by certain shared characteristics as noted above, but the physical characteristics of virions vary with respect to their genome (e.g., chemical composition, size, and architecture) and the packaging of the genome (e.g., capsid shape, symmetry, surface projections, and presence or absence of an envelope). To provide a sense of the scope of this variability, some of the information drawn from the Ninth Report of the International Committee on Taxonomy of Viruses (King *et al.*, 2012) is summarized here. This summary includes those viruses classified to the genus level, and specifically excludes those with no known encapsidated stage.

In addition to the four physical configurations already mentioned (dsDNA, ssDNA, ssRNA, or dsRNA), viral genomes may also be distinguished based on their length, whether they

are circular or linear, and whether they are mono or multipartite. If multipartite, the segments may be packaged together in a single virion or they may be individually encapsidated. Monopartite genomes range from 1775 nucleotides (nt) of ssDNA for a member of the family *Circoviridae* to 1,259,197 base pairs (bp) of dsDNA for a member of the family *Mimiviridae*. The total genome length for multipartite viruses (sum of the length of all segments) ranges from 3100 bp dsRNA (in the family *Partitiviridae*) to $\geq 600,000$ bp dsDNA (in the family *Polydnaviridae*). The smallest individual segment of a multipartite genome in which the segments are packaged together is reported to be only 200 bp dsRNA (family *Reoviridae*), but is

more typically >600 nt or bp. For multipartite genomes in which the segments are packaged individually, the segments range from 923 nt ssDNA to 9800 nt ssRNA.

Describing all of the known viral morphologies in detail is beyond the scope of this article, but some examples are provided to illustrate the range of morphological types one may encounter (Figure 3). These include the familiar polyhedral (often icosahedral) capsids, which may be isometric or elongated, and may be enveloped or not. A number of viruses appear to be spherical, but have polyhedral symmetry in their construction from subunits. Among the viruses infecting *Bacteria* and *Archaea*, are those that have a polyhedral capsid

Figure 3 Examples of some of the morphological diversity among viruses. (a)–(f) Show virions with capsids having icosahedral symmetry. (a)–(c) Illustrate the types of tails that are observed among virions in the order *Caudovirales* and (c) also illustrates a prolate icosahedron. (d) and (e) Illustrate the range in size observed among virions with isometric capsids and represent the largest and smallest viruses recorded. (f)–(h) and (j)–(m) represent viruses in which the capsid is enclosed in a membrane. (g) Shown in cut away to reveal the rod-shaped capsid within and (h) illustrates a pleomorphic virion. (h) Illustrates a filamentous virus with helical symmetry. (j)–(m) Illustrate some of the other unusual morphologies of virions. The taxa in which virions with these morphologies may be found are: (a) *Podoviridae*, (b) *Siphoviridae*, (c) *Myoviridae*, (d) *Mimiviridae*, (e) *Parvoviridae*, (f) *Herpesvirales*, (g) *Nimoviridae*, (h) *Paramyxoviridae* (also *Bunyaviridae*, *Arenaviridae*, and *Coronaviridae*), (i) *Inoviridae* (also *Closteroviridae*, *Alphaflexiviridae*, and *Betaflexiviridae*), (j) *Rhabdoviridae*, (k) *Ampullaviridae*, (l) *Poxviridae*, and (m) *Fuselloviridae*.

joined to a proteinaceous tail. The tail may be short and stout, long, and flexible, or long and contractile. Other viruses with helical symmetry take the form of filaments or rods. The presence of an external envelope (usually derived from membranes of the host cell) can result in a virion morphology that differs from the nucleocapsid within. These virions may be spheres, prolate spheres, or pleomorphic. Other viruses have shapes reminiscent of bullets, bricks, bottles, and lemons. In addition to the overall morphology, viruses can vary in the number and position of peplomers, or glycoprotein spikes, on the surface, which are involved in recognition of, and entry into, an appropriate host cell.

One hallmark of viruses is their exceptionally small size. An electron microscope is required to resolve the morphological details of viruses, but some (e.g., *Acanthamoeba polyphaga mimivirus*) are just large enough ($\geq 0.5 \mu\text{m}$) to be discernible with a light microscope. Among those viruses having isometric capsids, diameters of individual virions range from 17 to 500 nm. The thinnest filamentous viruses (in the family *Ophioviridae*) have a diameter of approximately 3.5 nm, but can be up to 3200 nm long. Because of the disparate morphologies of viruses, it can be useful for comparative purposes to calculate equivalent spherical diameters from the estimated viral volumes. In the case of multipartite genomes,

Figure 4 The relationship between genome length and capsid size. Average values of total genome length and equivalent spherical diameter were calculated for currently classified virus families using data reported in the Ninth Report of the International Committee on Virus Taxonomy (King *et al.*, 2012) and other literature data. The data are coded by whether the virions are enveloped or not (a), the type of nucleic acid contained in the virion (b) or the domain of life that serves as the host for the virus (c).

the total genome length is reported as the sum of the length of all segments. For viruses in which the segments of a multipartite genome are packaged separately, total virus volume to be the sum of the volumes of the set of virions that contain one complete set of genome segments has been considered. Equivalent spherical diameter (and thus virion volume) increases as a function of genome length regardless of the morphotype, but there is considerable scatter in the relationship (Figure 4). Envelopes, by adding an extra layer, tend to increase diameter of a virus for a given genome size (Figure 4(a)). Unenveloped, isometric viruses are noteworthy in that they represent both the smallest and the largest classified viruses both in terms of genome size and equivalent spherical diameter. The genome and capsid size distributions differ among viruses containing different types of nucleic acids, with ssDNA-containing viruses being the smallest, and dsDNA-containing viruses being the largest (Figure 4(b)). The size range also varies by host type (Figure 4(c)). Viruses infecting members of the domain *Archaea* have the narrowest range of capsid and genome size, while those infecting members of the domain *Eukaryota* have the widest range.

Viral infections have been reported in organisms representing the entire spectrum of life on the planet. In some cases, viral infections are only known from the observations of virus-like particles inside cells using an electron microscope, but viruses have also been isolated and characterized from members of all the domains and kingdoms of life. The number of different viruses confirmed to infect any given organism typically increases in proportion to the effort put into the search. Hundreds of human-infecting viruses have already been identified, for example, and scientists continue to discover more for our species. It thus appears that every species on earth is susceptible to infection by many distinct viruses. The phylogenetic breadth represented by the different types of organisms a virus can infect is referred to as its host range. Some viruses are able to infect many different hosts (broad host range), but often viruses appear to be rather specific (narrow host range). Host range is always construed in a relative sense, since the number and types of organisms tested is not standardized and a definitive host range determination is not empirically achievable. Despite the uncertainties stemming from variable and incompletely defined host ranges, the existing host range studies suggest that viruses are probably much more diverse than the entire spectrum of cellular life.

Viruses in the Sea

Viruses can be found wherever life is found and in seawater they outnumber *Bacteria*, *Archaea*, and *Eukarya* combined by an order of magnitude or more (Wommack and Colwell, 2000; Suttle, 2007). The concentration of virions in surface seawater in the open ocean is on the order of 5–10 billion per liter (Figure 5). Their concentration declines with depth, but viruses are present in the deepest waters sampled (>4000 m). The concentration of virions in surface marine sediments is typically even higher than in the immediate overlying waters. As in the water column, viruses become less abundant with depth in the sediment, but remain detectable to depths

Figure 5 Idealized plot of the concentrations of viruses and cells in open ocean seawater and sediments. Sediments are indicated by the shaded area. Sediment depth (in bold) starts over from zero at the sediment–water interface and is plotted at a different scale for clarity. “Cells” refers to all cells, but these numbers are dominated by bacteria and archaea. The numbers shown are approximate and concentrations at a given depth can vary by an order of magnitude depending on location. Concentrations tend to be higher in areas of high productivity such as the coastal zone.

>100 m below the seafloor (Bird *et al.*, 2001) and in sediments with estimated ages of hundreds of thousands of years or more (Middelboe *et al.*, 2011).

Virions suspended in seawater are a component of the marine plankton and are therefore often referred to as viroplankton. Those in sediments are sometimes referred to as viriobenthos (Danovaro *et al.*, 2008). Plankton ecologists find it convenient at times to refer to plankton according to which of seven different size categories they belong. Because of their small size, most of the viruses in seawater are members of the smallest named size category, the femtoplankton (0.02–0.2 μm), but larger viruses are also part of the picoplankton (0.2–2 μm), a size class that also includes almost all of the bacteria and archaea and the smallest protists (Figure 6).

Viral infections have been reported for a broad range of marine organisms (Munn, 2006) and these infections have wide-ranging effects on everything from evolution, ecology, and ocean biogeochemistry (Fuhrman, 1999; Rohwer and Vega Thurber, 2007) to human health and economics. Viral infections of phytoplankton, the foundation of the marine

Figure 6 Viruses as members of the marine plankton. As a group, viruses are the smallest and most abundant members of the plankton and an electron microscope is required to reveal their details. Plankton are often named by the size category to which they belong, but may also be referred to in functional categories such as virioplankton, phytoplankton, and zooplankton.

food web, affect how much of the ocean's primary production is transferred to higher trophic levels (Brussaard, 2004). Large increases in phytoplankton concentrations (blooms) are a common phenomenon in the ocean and these periodic increases in primary production serve as a critical food supply for life in the sea. Viruses also spread more easily through populations at high density, however, and phytoplankton blooms can be decimated by the rapid spread of viral infection. Lysis of phytoplankton decreases the efficiency with which they are consumed by grazers and much of the primary production is instead decomposed by bacteria (Bratbak *et al.*, 1998). Bacteria are themselves susceptible to viral infections and viral lysis of bacteria likewise diverts material and energy from protistan grazers, which favors further growth and respiration by other uninfected bacteria (Middelboe *et al.*, 1996). It thus appears that the net effect of lytic viral activity in the marine food web is to decrease the amount of carbon that reaches higher trophic levels (e.g., fish) while increasing the amount of carbon, which is respired by the bacteria (Fuhrman, 1992; Murray and Eldridge, 1994).

From the perspective of humans, viruses could be lamented as reducing the efficiency of wild fisheries, but by how much is unknown. In any case, there is little to be done about the persistent, ubiquitous influence of viruses on the ocean's food web; it is an inescapable feature of the natural cycle of life in the sea. However, viruses are a legitimate human concern with tangible economic consequences when they cause death and disease among farmed marine species such as shrimp and fish. As wild fisheries become increasingly threatened by overexploitation, humans are relying more heavily

on aqua- and mariculture as a source of protein. Intensive mariculture involves growth of single species at high densities, which, unfortunately, is a condition under which viral and other diseases can easily spread within the farm and from the farm to wild populations. The economic losses resulting from viral diseases in aquaculture are estimated to be in the billions of dollars annually (Walker and Winton, 2010) so there is a strong incentive to find solutions to combat viral diseases in commercially exploited marine species.

Life in the sea is very diverse, with representation of most of the major types of life on the planet. As one might then expect, the diversity of viruses in the sea is also broad (Breitbart *et al.*, 2007). Among viruses infecting the marine organisms, members of all Baltimore groups except for Group VII have been found so far (Table 1). The next section is a synopsis of the viruses belonging to these groups that have been isolated and characterized.

Taxonomic Diversity among Marine Viruses

This section is organized first by Baltimore Group, then by order (where one has been defined), then by family. Specific genera within a family are noted in some cases where it seems of particular interest. The taxonomic groups represented are, for the most part, restricted to those explicitly mentioned in the most recent report of the ICTV (King *et al.*, 2012), but some information is included from other sources and proposals that have been accepted since the report was completed. For the purposes of this presentation, a virus was

Table 1 Families and subfamilies of viruses for which marine isolates have been described

Group	Genome		Taxonomy			Marine hosts	
	Type	Segments	Order	Family	Subfamily	Types	Names
I	dsDNA	Mono	Caudovirales	Myoviridae	–	B	Cyanobacteria and proteobacteria
				Podoviridae	–	B	Cyanobacteria and proteobacteria
				Siphoviridae	–	B	Cyanobacteria and proteobacteria
			Herpesvirales	Alloherpesviridae	–	V	Fish
				Herpesviridae	Alphaherpesvirinae	V	Turtle
					Gammaherpesvirinae	V	Seal
			Unassigned	Malacoherpesviridae	–	I	Oyster
				Adenoviridae	–	V	Fish
				Corticoviridae	–	B	Bacteria
				Iridoviridae	–	V	Fish
				Mimiviridae	–	Pr	Heterotrophic protist
				Nimaviridae	–	I	Shrimp and crab
				Papillomaviridae	–	V	Porpoise and dolphin
				Phycodnaviridae	–	Pr	Micro- and macroalga
				Poxviridae	–	V	Marine mammals and birds
				Unassigned	–	Pr	Microalga
II	ssDNA	Mono	Unassigned	Anelloviridae	–	V	Sea lion

				Unassigned	–	Pr	Labrynthulid and microalga
		Mono	Unassigned	Astroviridae	–	V	Sea lion and dolphin
				Caliciviridae	–	V	Seals and whales
		Bi		Nodaviridae	–	V	Fish
		Mono		Togaviridae	–	V	Fish and mammals
V	ssRNA (–)	Mono	Mononegavirales	Paramyxoviridae	Paramyxovirinae	V	Seals and whales
				Rhabdoviridae	–	V	Fish
		Multi	Unassigned	Orthomyxoviridae	–	V	Fish, sea birds, seals, and whales
VI	ssRNA (+)	Mono	Unassigned	Metaviridae	–	I, V	Sea urchin and fish

Viruses are presented by Baltimore Group, genome type, and taxonomy to the subfamily level along with the type (B, bacteria; Pr, protist; I, invertebrate; V, vertebrate) and common names of marine hosts.

considered marine if it infects an organism commonly referred to as marine. This includes organisms for which the entire life cycle is completed in the ocean, but also sea turtles (marine reptile), a variety of birds such as gulls, terns, cormorants, and pelicans (marine birds) as well as seals and sea lions (marine mammals). The general characteristics of the virions in each taxon and the types of marine organisms they infect are noted.

Group I: dsDNA Viruses

The dsDNA virus isolates known to infect marine organisms are assigned to 13 of the 30 families in Baltimore Group I. Three families are members of the order *Caudovirales*, another three are members of the order *Herpesvirales*, and six families are not assigned to an order. A number of viruses infecting marine plankton have also not yet been assigned to a family.

Order Caudovirales

The viral order *Caudovirales* contains three related families of tailed viruses, all of which infect bacteria or archaea. Members of this order have nonenveloped capsids with icosahedral symmetry, but these may be isometric or prolate with diameters ranging from around 40–145 nm in diameter. Helical tails (10–355 nm long and 5–18 nm wide) aid in attachment to the host cell and serve as a conduit through which the viral genome is delivered to the interior of the cell. The tail structure serves as a taxonomic character that divides the order into the families *Myoviridae*, *Podoviridae*, and *Siphoviridae* (Figure 3(a)–3(c); Ackermann, 2006). Marine representatives can be found in all three of these families, but marine isolates reported to date are restricted to those infecting bacteria, probably because isolates of marine archaea remain so rare. Members of all three families are very common in seawater.

Family Myoviridae

Viruses in this family are characterized by having a long (50 to more than 200 nm) hollow tail with a neck and a contractile sheath. Because of the sheath, the tails of these viruses are thicker (16–18 nm) than those of other caudovirids (Figure 3(c)). Myovirids that infect marine bacteria, particularly bacteria in the phylum *Gammaproteobacteria*, have been classified, but many more marine isolates are known. These include a large number of isolates infecting cyanobacteria in the genera *Prochlorococcus*, and *Synechococcus* (Sullivan *et al.*, 2010). Although there is considerable overlap, the genomes and capsids of myovirids tend to be larger than those of the other two families in this order.

Family Podoviridae

Viruses in this family are characterized by the presence of a short, noncontractile tail that is 10–48 nm long and about 8 nm wide (Figure 3(a)). Podovirids appear to be the most numerous of all tailed phages in the marine environment. Podovirids infecting marine bacteria in the phyla *Alpha*- and *Gammaproteobacteria* have been officially classified by the ICTV, but many more isolates infecting a range of bacteria exist, including podovirids infecting *Prochlorococcus* and *Synechococcus* (Sullivan *et al.*, 2003).

Family Siphoviridae

Viruses in this family have a long, noncontractile tail that is around 100 to >300 nm long, and 5–10 nm wide (Figure 3(b)). These long, unsheathed tails often appear to be quite flexible, displaying bends and curves in electron micrographs.

Order Herpesvirales

Members of the order *Herpesvirales* have a large icosahedral capsid enclosed in a tegument and a lipid bilayer membrane (Figure 3(f)). The genome ranges from 125,000 to 295,000 bp. Capsids are around 125 nm, but the entire virion is closer to 200 nm in diameter. These viruses are very widespread in the vertebrates. Examples of herpesvirids infecting marine vertebrates are known in all three families of the order (Davison *et al.*, 2009).

Family Alloherpesviridae

Members of this family include those that infect fish and amphibians. Marine and estuarine representatives are in the genus *Ictaluvirus* and include those that infect catfish, sturgeon, salmon, and cod (Hanson *et al.*, 2011).

Family Herpesviridae

This family consists of genetically related herpesvirids that infect reptiles, birds, and mammals. Marine representatives have been assigned to two of the three subfamilies (*Alpha*- and *Gammaherpesvirinae*), but are not yet assigned to a genus. Marine hosts include sea turtles, seals, sea lions, dolphins, and whales (Maness *et al.*, 2011).

Family Malacoherpesviridae

This new family consists of a single genus (*Ostreavirus*) and species (*Ostreid herpesvirus 1*). This virus infects oysters and is the only herpesvirid identified so far that infects an invertebrate.

Families Not Assigned to an Order

Family Adenoviridae

Members of this family are nonenveloped and have a capsid 70–90 nm in diameter with icosahedral symmetry and a genome between 25,000 and 50,000 bp. Adenovirids infect a wide variety of vertebrates. There are a number of reports of infections by adenovirids in marine mammals (pinnipeds and cetaceans) and in gulls, but none have been isolated and officially classified. Sea lions may be a host for canine adenovirus. The only reported fish adenovirus is in the genus *Ichtadenovirus* with the sole representative being *Sturgeon adenovirus A*, which infects white sturgeon. Although not truly marine, the sturgeon habitat includes brackish coastal waters.

Family Corticoviridae

This family is represented by a single genus (*Corticovirus*) and a single species (*Pseudoalteromonas phage PM2*) that infects a marine bacterium (Espejo and Canelo, 1968). The virion has an icosahedral capsid 57 nm in diameter, no tail, and a lipid bilayer membrane interior to the capsid (Harrison *et al.*, 1971). The genome in the virion is supercoiled with a length of 10,079 bp (Männistö *et al.*, 1999). Although only one species has been classified at present, related sequences have been detected within the genomes of a variety of bacteria suggesting that they could be prevalent in the marine environment (Krupović and Bamford, 2007).

Family Iridoviridae

Members of this family have a large icosahedral capsid (120–200 nm diameter) and a large genome (around 100,000 to 200,000 bp). They infect invertebrates (arthropods) and vertebrates (amphibians, reptiles, and fish). Those infecting invertebrates are nonenveloped while those infecting vertebrates acquire a lipid envelope that derives from the host cell membrane during virion budding. Members of two of the five genera in this family (*Lymphocystivirus* and *Megalocytivirus*) infect marine fish.

Family Mimiviridae

This is a relatively new family of viruses, the members of which have unusually large genomes and icosahedral capsids. The first representative to be fully sequenced, *Acanthamoeba polyphaga mimivirus* (APMV) infects a freshwater amoeba (Scola *et al.*, 2003). At the time of its discovery, it was the largest known virus with a genome of 1,181,549 bp and a capsid diameter of 500 nm (Figure 3(d)). The virus is densely covered with hair-like fibrils that extend its effective diameter to 750 nm. Recently, another virus related to APMV with a larger genome (1,259,157 bp), but smaller capsid (440 nm) was isolated from a marine sample using several freshwater *Acanthamoeba* species as hosts (Arslan *et al.*, 2011). The natural host of this new isolate, named *Megavirus chilensis*, is unknown, but is presumed to be a marine or estuarine protist. This is the largest viral genome known at the present time.

Family Nimaviridae

This family consists at present of a single genus (*Whispovirus*) and species (*White spot syndrome virus*). Virions consist of a rod-shaped nucleocapsid (approximately 65–70 × 300–350 nm) enclosed in a tegument and a trilaminar envelope. The overall

virion dimensions are 120–150 nm in diameter and 270–290 nm in length. The virion is unusual in having a thread-like appendage that gives it the superficial appearance of a bacterium with a polar flagellum (Figure 3(g)).

Family Phycodnaviridae

The members of this family that have been officially classified so far have large icosahedral capsids (around 100–200 nm diameter) with no outer envelope and genome sizes ranging from approximately 100,000 to 500,000 bp. These viruses infect photosynthetic protists (micro and macroalgae) in both freshwater (genus *Chlorovirus*) and the marine environment (genera *Coccolithovirus*, *Phaeovirus*, *Prasinoviruses*, *Prymnesioviruses*, and *Raphidoviruses*). Members of the genus *Phaeovirus* infect filamentous brown algae, but all others infect unicellular plankton.

Family Poxviridae

The capsids of poxvirids are enveloped and brick shaped or ovoid with tubular surface processes (Figure 3(l)). They vary from 200 to 450 nm in length, 140–280 nm in width, and 140–280 nm in thickness. The genomes are linear dsDNA ranging from 130,000 to 380,000 bp. Members of this family infect a wide range of hosts. The poxvirids infecting vertebrates are in the subfamily *Chordopoxvirinae*, which contains nine genera. The subfamily *Entomopoxvirinae* comprises three genera, the members of which infect various insects. The family is well known for the serious human disease caused by one of its notorious members, small pox (now eradicated). In the marine realm, poxviruses have been identified in penguins, seals, sea lions, dolphins, and whales, but none of these have been officially classified.

Unassigned

Several new viruses infecting marine heterotrophic and phototrophic protists have been isolated and described, for which the taxonomic positions remain unclear. A large (300 nm) virus, CroV, that infects *Cafeteria roenbergensis* (Garza and Suttle, 1995) is the first isolate that infects a phagotrophic marine protist. Based on the large genome size (750,000 bp) and specific sequence of the DNA polymerase of CroV, it may belong to the family *Mimiviridae* (Fischer et al., 2010). A number of other virus isolates infecting photosynthetic marine protists (*Chrysochromulina ericina* virus 01B, *Phaeocystis pouchetii* virus 01, and *Pyramimonas orientalis* virus 01B) have capsids closer in size to phycodnavirids (140–220 nm), but their DNA polymerase genes place them closer to APMV and CroV, suggesting they may also be members of the *Mimiviridae*.

A large virus (200 nm diameter, 350,000 bp genome) was isolated that infects the bivalve-killing dinoflagellate, *Heterocapsa circularisquama* (Nagasaki et al., 2003). The DNA polymerase sequence of this isolate is very similar to that of African swine fever viruses in the genus *Asfivirus*, which is the sole genus in the family *Asfarviridae*. It is, therefore, highly divergent from other dsDNA viruses infecting phytoplankton and a new genus name, *Dinodnavirus*, has been proposed for this virus.

Group II: ssDNA Viruses

Families Not Assigned to an Order

Family Anelloviridae

Members of this family have a nonenveloped icosahedral capsid approximately 30 nm in size and a circular genome ranging in size from 2000 to 3900 nt. They appear to be widespread in mammals, but their involvement in specific diseases remains unproven. Novel anellovirids have recently been detected by metagenomic analyses of lung tissue from seals and sea lions (Ng et al., 2009, 2011), but these have yet to be approved as species.

Family Circoviridae

This family is comprised of two genera (*Circovirus* and *Gyrovirus*) known to infect birds and swine, although distantly related viruses have been described in primates. The virions are nonenveloped and appear spherical with icosahedral symmetry. The capsid diameter is 20.5–25 nm and the genome ranges from 1775 to 2300 nt. The only classified member so far that might be considered marine is the gull circovirus in the genus *Circovirus*.

Family Inoviridae

Virions in this family are filaments (Figure 3(i)) or rods with helical symmetry with a circular genome ranging from 4500 to 12,400 nt in length. Those in the genus *Inovirus* are long (700–900 nm) and thin (7 nm) and infect gammaproteobacteria, while those in the genus *Plectrovirus* (10–15 nm wide and 70–280 nm long) infect Gram-positive bacteria. Among the known hosts of inovirids are members of the bacterial genus *Vibrio*, which are common in coastal estuarine and marine waters. Inovirids cause persistent infections and are responsible for lysogenic conversion. The inovirid, *Vibrio cholerae* CTX ϕ , for example, codes for an enterotoxin that converts *Vibrio cholerae* into a human pathogen.

Family Microviridae

Virions in this family have a small, nonenveloped capsid approximately 25–27 nm in diameter and a circular, positive-sense genome ranging in size from 5300 to 6100 nt (genus *Microvirus*) or from 4400 to 4900 nt (genera *Chlamydiamicrovirus*, *Bdellomicrovirus*, and *Spiromicrovirus* in the subfamily *Gokushovirinae*). The hosts for members of the genus *Bdellomicrovirus*, are bacteria in the genus *Bdellovibrio*. *Bdellovibrio* spp. are predatory bacteria found in a range of freshwater, estuarine, and marine habitats. All strains of bdellomicroviruses isolated so far have been from freshwater. However, there is evidence from metagenomics that additional members of the *Gokushovirinae* are widespread in the ocean (Angly et al., 2006; Tucker et al., 2011). Sequence comparisons indicate that these viruses are distantly related to known chlamydiamicroviruses and bdellomicroviruses, but their hosts have not yet been identified.

Unassigned

Several genetically similar ssDNA viruses infecting diatoms in the genus *Chaetoceros* have been isolated. The virions are nonenveloped and have an icosahedral capsid ranging in size from 30 to 38 nm and a genome around 6000 nt in length.

Although these viruses do not yet belong to an official family, a new genus, *Bacilladnavirus*, has been approved to accommodate this group of viruses.

Group III: dsRNA Viruses

Families Not Assigned to an Order

Family Birnaviridae

There are four genera in the family *Birnaviridae*. The icosahedral particles of birnavirids are 65 nm in diameter, nonenveloped and are composed of a single capsid protein. The genome consists of two linear segments of dsRNA approximately 5900–6900 bp in total length that encodes a polymerase and a large structural polyprotein that is cleaved post-translationally. Birnavirids infect rotifers, insects, fish, and birds and are globally distributed. In the marine environment, aquabirnaviruses cause disease in salmonids, amberjack (yellowtail), bream, and cod among other fishes, and even molluscs and crustaceans.

Family Reoviridae

The family *Reoviridae* has fifteen genera divided among two subfamilies, the *Spinareovirinae* that include viruses that have turret-like proteins projecting from their capsid, and the *Sedoreovirinae*, the reovirids without turrets. The virions in this family are nonenveloped icosahedrons that range from 49 to 100 nm in diameter. Reovirids are distinctive in that their capsid can be composed of as many as three concentric protein shells that surround from 9 to 12 segments of dsRNA, that together range between 18,500 and 33,300 bp in total length. The viruses in this family infect a wide range of multicellular organisms including protists, fungi, plants, insects, reptiles, and humans. The dsRNA virus *Micromonas pusilla* reovirus (MprV) from the genus *Mimireovirus* was one of the first marine RNA viruses isolated and it infects a marine protist (Brussaard *et al.*, 2004). The host, *M. pusilla*, is a small (<2 µm), autotrophic flagellate considered the most abundant picoeukaryote in the global oceans (Not *et al.*, 2004). Species of bivalves and finfish are subject to infection from reovirids in the genus *Aquareovirus*, while orbiviruses have been found in seabirds (e.g., murre, puffins, and razorbills) and cardoreoviruses in crabs.

Group IV: Positive-Sense ssRNA Viruses

Order Nidovirales

The order *Nidovirales* is divided into three families, two subfamilies and seven genera. Virions in this order range widely in size from 50 to 200 nm, but all are enveloped. The genome of a nidovirad is a single, linear molecule of RNA that ranges in size from 12,700 to 29,100 bp and has a 5' cap and a poly(A) tail that extends from the 3' end. The gene order is highly conserved, with open reading frames (ORFs) nearest the 5' end encoding the replicase, followed by 3–12 structural proteins. The genomes of viruses in the *Nidovirales* contain a characteristic –1 frameshift that is involved in the regulation of viral protein production during replication. Members of this order are the largest RNA viruses known to date, both in genome and particle size.

Family Roniviridae

The genus *Okavirus* is the only genus in the family *Roniviridae*. The virions of ronivirids are enveloped, bacilliform in shape, vary in size from 150 to 200 nm, and are studded with spike-like glycoprotein projections that have bulbous distal ends. The genome of these viruses has features typical of the order *Nidovirales* and can be quite large for an RNA virus, exceeding 26,000 nt in length. The genome configuration, particularly in the structural genes, as well as the absence of a discrete structural membrane protein gene, distinguishes ronivirids from other viruses in the order. Viruses in the family *Roniviridae* infect the giant tiger shrimp and the blue shrimp.

Order Picornavirales

The sprawling order of the *Picornavirales* contains five families, two subfamilies, 24 genera, and approximately 120 species of viruses. Picornavirids are “picorna-like” in that they have similar features to viruses in the family *Picornaviridae*. Members of the order have a nonenveloped icosahedral capsid that ranges in diameter from 22 to 30 nm. The linear, ssRNA genome is 7000–15,500 nt in length and encodes a polyprotein that is post-translationally processed. Picornavirids also have in common a conserved nonstructural gene order and a small protein covalently linked to the 5' end and a 3' end poly(A) tail. These viruses infect a wide range of eukaryotes, including humans. *Picornavirids* of note include human enterovirus C, which causes poliomyelitis, human rhinovirus, responsible for the common cold, and Israeli acute paralysis virus, which has been linked to honey bee colony collapse disorder.

Family Dicistroviridae

The family *Dicistroviridae* has two recognized genera, the cricaviruses and the aparaviruses. The particles of dicistrovirids are nonenveloped icosahedra approximately 30 nm in size. The genome is a single molecule of linear RNA that can be from 8500 to 10,000 nt in length and encodes two polypeptides, or cistrons (*ergo* the name of the family). Dicistrovirids infect only invertebrates, including aphids, bees, and butterflies. In the marine environment, Taura syndrome virus (TSV), an aparavirus, infects penaeid shrimp. TSV epidemics have been responsible for high rates of mortality in shrimp farms.

Family Marnaviridae

Heterosigma akashiwo RNA virus (HaRNAV) is the only member of the *Marnaviridae*. *Heterosigma akashiwo*, the host of HaRNAV, is a small, motile photosynthetic protist that is a common member of the temperate coastal phytoplankton community. During times when surface waters are stratified as a result of higher sea surface temperatures and low winds, *Heterosigma akashiwo* is capable of forming immense blooms that can cause extensive fish kills. These toxic blooms affect the fish farming industry in the fjords of western Canada, and Scandinavia in particular (Smayda, 1998). In 2003, Tai and colleagues isolated HaRNAV, the first RNA virus reported to infect a protist (Tai *et al.*, 2003). HaRNAV has a nonenveloped, icosahedral capsid that is approximately 25 nm in diameter. The burst size of HaRNAV is estimated to be 20,000 viruses per cell (Lawrence *et al.*, 2006). The linear ssRNA genome of HaRNAV is 8600 nt in length and is monocistronic – unlike

AuRNAV (see Proposed Family *Labyrnaviridae*), the bacillarnaviruses, TSV (see Family *Dicistroviridae*), and HcRNAV (see Proposed Family *Alvernnaviridae*). However, the HaRNAV genome has the same gene order as the other marine ssRNA viruses with the nonstructural genes nearest the 5' end of the genome followed by the structural genes. Phylogenies based on the conserved domain sequences from HaRNAV and the corresponding regions of other viruses place HaRNAV outside previously characterized virus taxa within the order *Picornavirales*.

Proposed genus *Bacillarnavirus*

The genus *Bacillarnavirus* has not been assigned to a family within the order *Picornavirales*. It has three recognized members thus far, *Rhizosolenia setigera* RNA virus (RsetRNAV), *Chaetoceros tenuissimus* Meunier RNA virus (CtenRNAV), and *Chaetoceros socialis* f. *radians* RNA virus (CsfrRNAV) all of which infect marine diatoms. Diatoms are widely distributed, highly diverse, and are among the most abundant eukaryotes in the ocean. They form a large fraction of the total marine primary producers and are thus significant contributors to the cycling of energy in the ocean (Graham and Wilcox, 2000). The hosts of CtenRNAV and CsfrRNAV are members of the genus *Chaetoceros*, a group of chain-forming diatoms that can form blooms associated with fish kills. The two viruses have icosahedral symmetry and have ssRNA genomes that are dicistronic and approximately 9500 nt in length. CtenRNAV has an estimated capsid diameter of 31 nm (Shirai *et al.*, 2008), while that of CsfrRNAV is only 22 nm (Tomaru *et al.*, 2009). A striking difference between the two viruses is that CtenRNAV has an estimated burst size of 10,000 virions while CsfrRNAV produces approximately 66 per lytic event. RsetRNAV was the first virus brought into culture that infects a diatom. Like CtenRNAV and CsfrRNAV, RsetRNAV has an icosahedral capsid (approximately 32 nm in diameter), replicates in the cytoplasm and has a positive-sense ssRNA dicistronic genome approximately 8900 long (Nagasaki *et al.*, 2004). The genomes of all three RNA viruses have a similar gene order, with the structural genes nearest the 5' end, followed by the helicase, protease, and replicase and terminating in a poly(A) tail. Alignments of the replicase genes of these viruses clearly demonstrate that they are closely related and form a well-supported monophyletic clade (Tomaru *et al.*, 2009).

Proposed Family *Labyrnaviridae*

Aurantiochytrium RNA virus (AuRNAV) is the only member of the family *Labyrnaviridae*. AuRNAV infects the thraustochytrid *Aurantiochytrium* sp. Thraustochytrids are single-celled marine organisms that were once thought to be fungi, but are now recognized as a class of protists. These organisms are capable of feeding directly through absorption and are involved in the degradation of detritus (Raghukumar, 2002). Like HcRNAV (see Proposed Family *Alvernnaviridae*) and the bacillarnaviruses, AuRNAV has a small (roughly 25 nm), nonenveloped icosahedral capsid. AuRNAV replicates in the cytoplasm and has a phenomenal burst size of approximately 60,000 particles per lytic event (Takao *et al.*, 2005). The genome of AuRNAV is a single molecule of RNA 9000 nt in length with a poly(A) tail. The three ORFs of the AuRNAV genome encode the capsid proteins, nonstructural genes and a protein of unknown

function (Takao *et al.*, 2006). Interestingly, AuRNAV produces subgenomic RNA during replication. Although the specific mechanism is unknown, this suggests that the AuRNAV genome does not possess an internal ribosome entry site structure that is characteristic of other picornavirids.

Families Not Assigned to an Order

Proposed Family *Alvernnaviridae*

The family *Alvernnaviridae* has a single representative at present, *Heterocapsa circularisquama* RNA virus (HcRNAV), which infects the eponymous dinoflagellate. The dinoflagellates are a diverse group of unicellular flagellates that are capable of deriving energy in a number of different ways, including through parasitism, photosynthesis, and predation. Dinoflagellates are found in marine and freshwater, sediments, snow and ice, and even inside other organisms. They are an important food source for plankton, a critical component of coral reefs, and can periodically form potent harmful algal blooms (Graham and Wilcox, 2000). *Heterocapsa circularisquama* is an armored, free-living protist that can form extensive blooms and these blooms have resulted in severe financial losses to the aquaculture industry (Matsuyama, 1999). HcRNAV particles do not have an envelope and are approximately 30 nm in diameter. The linear RNA genome of this virus is only 4400 nt long (Tomaru *et al.*, 2004). The two ORFs of the HcRNAV genome encode a protease, a replicase, and a single capsid protein (Nagasaki *et al.*, 2005). During the final stages of HcRNAV replication, the virus forms tightly packed crystalline arrays within the cell that result in the release of an estimated 20,000 viral particles during lysis (Tomaru *et al.*, 2004).

Family *Astroviridae*

The family *Astroviridae* includes two genera. The capsids of astrovirids have nonenveloped, spherical particles that range in size from 28 to 30 nm and are covered in mushroom-like projections involved in virus attachment and entry. The genome of these viruses is a single linear molecule of RNA that is generally from 6400 to 7700 nt long and terminates in a poly(A) tail. Like the calicivirids, the astrovirids produce a subgenomic RNA that encodes the structural proteins. Astrovirid infections cause gastroenteritis in a variety of birds and mammals, including humans. In the marine environment, members of the *Mamastrovirus* genus infect Bottlenose dolphins, and California and Steller sea lions.

Family *Caliciviridae*

There are five genera of viruses within the family *Caliciviridae*. Viruses in this family produce nonenveloped, icosahedral virions 27–40 nm in diameter that have distinctive cup-shaped depressions. The genome of these viruses is linear, ranges from 7300 to 8300 nt long and has a poly(A) tail. Unlike some other taxa of group IV viruses, the calicivirids make a subgenomic RNA that encodes the structural genes during replication. Humans, pigs, rodents, and cats, among other vertebrates are all infected by calicivirids. Viruses in the genus *Vesivirus* have been found to infect diverse marine mammals, including sea lions, cetaceans, and walrus. Vesiviruses exhibit a broad cell tropism and a broad host range. For example, vesiviruses isolated from marine mammals are capable of infecting pigs and humans (Green, 2007).

Family Nodaviridae

There are two genera in the family *Nodaviridae*. Viruses in this taxa are generally spherical in shape, (from 25 to 33 nm in diameter) and lack an envelope and discernible surface structure. The genome of nodavirids consists of two molecules of RNA (approximately 4500 nt in total length) that have 5' caps and lack poly(A) tails. Nodavirids are capable of infecting a variety of insect species including two species of *Aedes* mosquitos, in which they cause paralysis and death. Viruses in the genus *Betanodavirus* infect and cause disease in marine fish. Examples include flounder, grouper, and pufferfish, among others. In addition, several nodavirid-like viruses not yet approved by the ICTV infect prawns.

Family Togaviridae

This family comprises two genera, the alphaviruses and rubiviruses. While the *Alphavirus* genus has approximately 40 recognized members, the Rubella virus is the only member of the *Rubivirus* genus. The particles of these viruses are enveloped, spherical in shape and have an approximate diameter of 70 nm. The genome of a togavirid is a single strand of RNA that is from 7700 to 11,800 nt in length and has a 5' cap and a poly(A) tail. While most togavirids are transmitted via an arthropod intermediary, transmission of the alphaviruses that infect marine mammals and fishes do not appear to require a vector. Alphaviruses have been isolated that infect elephant seals, Atlantic salmon, and rainbow trout.

Group V: Negative-Sense ssRNA Viruses

Order Mononegavirales

The *Mononegavirales* is a large order of negative-sense single-stranded viruses that includes four families, two subfamilies, and 16 genera. Although the morphology of these viruses can vary widely (ranging from 80 to 805 nm in size), all virions are enveloped and most possess spike-like structures that are involved in attachment to and fusion with the host cell. The genomes of mononegavirids are linear and nonsegmented, range from 8900 to 19,100 kb in size, lack a 5' cap and a poly(A) tail, have a characteristic gene order (wherein from the 3' end, core protein genes are followed by envelope genes and then the polymerase), and encode an RNA-dependent RNA polymerase whose sequence is highly conserved. During replication, each cistron is transcribed utilizing a stop-start mechanism starting at a single promotor region located on the 3' end. The *Mononegavirales* is a taxon of particular relevance to human health, because it includes virulent human pathogens such as the Ebola virus, rabies virus, and measles and mumps viruses, but also includes many representatives infecting marine organisms.

Family Paramyxoviridae

The paramyxovirids are viruses of vertebrates that are responsible for notorious diseases in humans and animals such as measles, mumps, pneumonia, rinderpest, and Newcastle disease. The family is organized into two subfamilies comprised of seven genera. The virions of paramyxovirids are spherical in shape and approximately 150 nm in diameter. The genome of these viruses is a single molecule of negative-

sense RNA that can be from 13,300 to 18,200 kb in length. All genomes of paramyxovirids encode a protein, creatively named "F" which causes the fusion of the virus and cell membranes at neutral pH. An interesting characteristic of the replication of paramyxovirids is the "rule of six." This rule alludes to the fact that the efficiency of RNA replication in these viruses is severely diminished if the number of nucleotides in the RNA template being replicated is not exactly a multiple of six. It is believed that the precise packaging requirements of the virus drive this surprising requirement (Lamb and Parks, 2007). The Cetacean morbillivirus and the Phocine distemper virus are species in the genus *Morbillivirus* that infect marine mammals, while the Newcastle disease virus has been isolated from the common murre (Lang et al., 2009).

Family Rhabdoviridae

More than 200 different strains of rhabdovirids have been isolated from plants, invertebrates and vertebrates. The most distinctive feature of this family of viruses is that they all possess a bullet or rod-like morphology (Rhabdo from Latin, *rhabdos*, "rod") that can be from 100 to 430 nm in size (Figure 3(j)). The genome of a rhabdovirid is a single molecule of negative-sense RNA that can be from 11,000 to 14,900 kb in length. Viruses in the genus *Novirhabdovirus* infect diverse fishes, including salmon, flounder, and eels. Two novirhabdoviruses of note, infectious hematopoietic necrosis virus and viral hemorrhagic septicemia virus, are responsible for the mortality of significant numbers of wild and farm-raised salmon each year (Lang et al., 2009). The rhabdovirid Dolphin rhabdovirus-like virus was isolated from a white-beaked whale in the North Sea (Bressem et al., 1999).

Families Not Assigned to an Order

Family Orthomyxoviridae

The virions of orthomyxovirids are enveloped, spherical in shape, and range in diameter from 80 to 120 nm (e.g., Figure 3(h)). They contain a negative-sense RNA genome composed of six to eight segments of different length that are in total from 10,000 to 14,700 kb in size. Because of their ubiquity and virulence, orthomyxovirids have been intensely studied since the early twentieth century. This research has resulted in an unprecedented understanding of the mechanisms of zoonosis and evolutionary history of these viruses. Analyses of genomic data suggest that wild aquatic birds may be the primary reservoir of the orthomyxovirids that now infect a wide range of vertebrates, including the human-infecting H1N1 strain responsible for the worldwide human pandemic of 1918 (Palese and Shaw, 2007). Of the five genera in the family, the genera *Isavirus* and *Influenzavirus A* have viruses that infect fishes and marine mammals.

Family Bunyaviridae

The family *Bunyaviridae* comprises five genera whose viruses infect vertebrates and plants primarily via an arthropod vector. Among other distinguishing features, bunyavirids have a genome comprised of three unique molecules of negative or ambisense ssRNA, that range in total size from 11,400 to 19,200 kb, that encodes four structural proteins. The particles of these viruses are pleomorphic and range in size from 80 to

120 nm (e.g., [Figure 3\(h\)](#)). The terminal sequences of the three genome segments are highly conserved among bunyavirids and play an important role during viral replication. Most bunyavirids are capable of replicating in both arthropods, where little cytopathogenicity occurs, and vertebrates, where they are cytolytic ([Plyusnin et al., 2012](#)). Mourilyan virus is a bunya-like virus that infects two penaeid prawns. Additional bunyavirids have been isolated that infect seabirds, including murres and puffins.

Group VI: Positive-Sense ssRNA Viruses that Replicate through a DNA Intermediate

Family Metaviridae

Metavirids blur the line between virus and retrotransposon in that only one of the species of virus in this family produces infectious extracellular particles (these virions are irregular in shape and range in size from 50 to 100 nm). Oddly, encapsidated particles are produced within the cytoplasm of the host cell and in most cases do not exit. Nevertheless, viruses in this family encode the hallmark genes (major capsid protein, reverse transcriptase, and integrase), share the same gene order, and have a similar genome length to retroviruses (5200–7600 kb). There are two known marine metavirids that infect the same species of pufferfish, the Takifugu rubripes Sushi virus (TruSusV) and Fugu rubripes Suzu virus (FruSuzV), classified in the genera *Metavirus* and *Semotivirus*, respectively.

Phenotypic and Genotypic Diversity of Marine Virioplankton

Detailed characterizations of cultivated viruses have been essential for developing a coherent viral taxonomy. This structure has brought order to the bewildering complexity of the viral world, but viral diversity as viewed through the lens of taxonomy has its limitations. The stringent requirements for establishing official taxonomic classifications mean that the process is slow and deliberate. The rate at which novel viruses can be identified far outstrips the rate at which they can be properly classified. Taxonomy also does not concern itself with relative abundance or biogeography, which is an issue of interest to ecologists. Microbial ecologists investigating viruses in the ocean have therefore been somewhat less concerned with taxonomic classifications than with practical measures of diversity. Some studies rely on cultivation (e.g., establishing host ranges), but many others have focused on quantifying abundance and diversity (phenotypic and genotypic) using cultivation-independent methods.

Host Range

The low-throughput of cultivation is a bottleneck in the characterization of viral communities, but the ability to propagate a virus in the lab allows one to collect ecologically relevant information that cannot be obtained any other way. One can determine, for example, in how many different types of cells the virus can replicate. Investigations of viruses with different host ranges can provide insight into the fitness

costs that must necessarily be incurred to offset the benefits of being able to infect a broader range of cell types. Although viruses are often classified as having a broad or narrow host range, such a semiquantitative conclusion is necessarily conditional, since not every possible host can be screened. Despite that limitation, host range analysis has been very enlightening, because it can be exquisitely sensitive in discriminating between strains and it does not require sophisticated or expensive technology. To perform this analysis, each viral isolate is tested for its ability to lyse a suite of organisms. Since viruses tend to be more or less host-specific, the suite of organisms tested should primarily consist of different strains of the same species or different species in the same genus, but testing more distantly related organism allows one to identify viruses with particularly broad host range. The more organisms one tests, the greater one's chance of discriminating between closely related viruses. Use of this technique with marine bacteria ([Moebus and Nattkemper, 1981](#); [Wichels et al., 1998](#)) has shown that the number of viruses infecting any given genus of marine bacterium is extraordinarily large.

Morphology

The subnanometer resolving power of the transmission electron microscope (TEM) allows one to discriminate fine structural details of individual virions. This power has been exploited to conduct qualitative surveys of marine viral diversity (e.g., [Frank and Moebus, 1987](#)) that hint at an extraordinary richness. Electron microscopy has been used for quantitative, comparative assessments of diversity in natural communities as well, but the resolving power cannot be fully exploited in this context for technical and economic reasons. Negative staining, which reveals the greatest detail of virions, is difficult to control and best suited to qualitative rather than quantitative assessments of diversity. Even with the greater uniformity provided by positive staining, it is difficult to confidently discriminate similar viruses in a mixed assemblage. A single virus may appear different depending on its orientation or as a result of damage or distortion during preparation. As a consequence of these limitations, quantitative surveys of morphological diversity have relied on classification into a handful of broad categories (e.g., <30, 30 to <60, 60 to <80, 80 to <100, and ≥ 100 nm). The results of TEM surveys indicate virus-like particles in the ocean are usually numerically dominated by those with capsid diameters in the range of 30–60 nm, but range in size from around 20 to 750 nm ([Gowing, 1993](#); [Weinbauer, 2004](#); [Børshiem, 1993](#)). Viruses in the ocean thus span a similar size range as that observed among all classified viruses (18–500 nm). A significant, but variable, proportion of the viruses in seawater enumerated by TEM have tails, suggesting that they belong to the order *Caudovirales* and infect bacteria or archaea ([Weinbauer, 2004](#)).

Genome Size

Genomes of viruses vary over orders of magnitude in length. Among marine viruses, for example they range from 3000 nt to 1,290,000 bp. Quantitative analysis of the genome length

distribution in a sample can therefore provide some sense of diversity (Klieve and Swain, 1993; Steward *et al.*, 2000; Wommack *et al.*, 1999). Because conventional electrophoresis can only resolve DNA if it is less than about 20,000–30,000 bp in length, pulsed-field gel electrophoresis (PFGE) has been used to analyze natural assemblages of viruses. The size range of virus genomes detected in seawater with this technique ranges from around 20,000 to > 500,000 bp. Under the right conditions, complex, fine-scale banding patterns can be seen, indicating that natural viral communities are quite diverse, but not all genome sizes are equally represented. In a wide variety of marine environments, the distribution of genome sizes appears to be multimodal, with peaks of genome copy numbers frequently occurring for sizes in the vicinity of 30, 55, and 60 kb. The peaks are broad, however, and there are bands detectable throughout the range. Bands > 100 kb are usually detected, meaning they contain a significant amount of DNA, but because there is more DNA per large genome, the copy number is low. The mean genome size of dsDNA viruses in seawater is around 50,000 bp, but the mode is closer to 30,000 bp. Because much of the DNA is clustered into several narrow size ranges, many genomes are not adequately resolved by PFGE. This method is therefore of limited value in quantifying viral diversity, especially richness, but remains a convenient means to track changes in community composition (Sandaa *et al.*, 2010).

Single-Gene Surveys

Investigation of the diversity of microbial communities was revolutionized with the development of methods for cultivation-independent molecular surveys. Development of the polymerase chain reaction was transformative because it provided a means to amplify only specific genes of interest from a complex background of DNA (Britschgi and Giovannoni, 1991). Analysis of the amplified material by sequencing or molecular fingerprinting allows one to determine how many variants of the targeted gene were present and thus evaluate genetic diversity. The small subunit ribosomal RNA gene has been the primary target for analyzing the diversity of cellular life, because of its many desirable properties including the fact that it is present in all cellular organisms (Olsen and Woese, 1993). Viruses, however, do not code for ribosomal proteins. Viruses are so diverse, in fact, that there is no single gene that can be used as a universal viral target. Nevertheless, one can identify genes that are present and sufficiently conserved within subgroups of viruses that they can be used to survey diversity for a portion of the viral community. For example, structural genes of myovirids (Fuller *et al.*, 1998; Filée *et al.*, 2005) and phycodnavirids (Larsen *et al.*, 2008), DNA polymerase genes of podovirids (Chen *et al.*, 2009; Labonté *et al.*, 2009) and phycodnavirids (Chen and Suttle, 1995), and the RNA polymerase gene of picornavirids (Culley *et al.*, 2003) have been used to assess the diversity of these various groups in the marine environment. Results from these surveys indicate that members of those viral groups are persistent and globally distributed, but within each group the specific sequence types detected and their relative abundance varies as a function of location, time, and depth. Comparing the viral

Figure 7 Comparison of the diversity among cultivated and uncultivated viruses. The extensive diversity of viruses revealed by single-gene surveys and how it compares to the diversity among viruses that have been classified is illustrated using marine picorna-like viruses as an example. A phylogenetic tree was created using partial sequences of the RNA-dependent RNA polymerase gene for picornavirid strains in culture (branches marked with a black circle at the tip) or those identified from single-gene surveys of seawater samples (unmarked branches). Groups of sequences identified by an arc and a letter contain representative members of established groups of picornavirids as follows: group A, *Secoviridae*; group B, *Bacillarnavirus*; group C, *Labyrnnaviridae*; group D, *Picornaviridae*; group E, *Dicistroviridae*; group F, *Marnaviridae*; group G, *Ifilaviridae*; and the outgroup H, *Potyviridae*.

gene sequences recovered by this cultivation-independent technique with homologous genes from viruses in culture has been very revealing. We now know that most of the viral diversity present in seawater is not represented in culture collections (Figure 7).

Metagenomics

There are a number of limitations implicit in the targeted gene approach. First, one recovers information only about variants of a single gene (usually just a portion of the gene). Second, those genes come from only a subset of the viral community, and third, creating a meaningful target in the first place requires at least some prior knowledge about the viruses being sought. Metagenomic analysis, in contrast, allows for a relatively unbiased sampling of all of the viral genomes present in a sample, with no prior knowledge of their sequences (Edwards and Rohwer, 2005). To analyze a viral metagenome, viruses are first harvested from a seawater sample, separated from cells and dissolved nucleic acids, then the viral nucleic acids are extracted. The extracted genomic material is then broken into random, small pieces for sequence analysis. For technical reasons, metagenomic analyses have so far tended to focus on either the DNA viruses or the RNA viruses present in a sample, but it is possible to analyze both at once.

After the analysis, one has a collection of sequence reads that derive from random fragments of the various viral genomes that were present in the original sample. Because one is sampling diversity across entire genomes, rather than a single gene, metagenomic analyses require much greater numbers of sequencing reads (thousands to millions) than are typical of single-gene surveys (tens to hundreds) to draw meaningful conclusions about diversity within a sample and how it compares to other samples. A first-order analysis one can perform is to compare each of the sequences that make up a metagenome to all of the sequences archived in various repositories to see if they are similar to genes that are already known. One can then classify each sequence according to its likely function and the type of organisms from which it might derive. In addition to analyzing each read independently, it is also informative to determine how many of the sequence reads derive from overlapping regions of the same genome, and can thus be reassembled into a single longer read. The higher the diversity in a sample, the lower is the probability that any two or more reads in the randomly selected pool of sequences that comprise the metagenome will overlap. By making a number of assumptions, one can estimate the diversity of the original sample from the assembly statistics for the metagenome (Angly *et al.*, 2005). Although metagenomics has its limitations (Steward and Rappé, 2007), it is providing many new insights into the genetic diversity of viruses in the environment (Kristensen *et al.*, 2010).

DNA-Containing Viruses

In metagenome analyses of marine DNA-containing viruses, most (around 75%) of the viral genes do not resemble any gene with a known function or which derive from a known organism. Among those sequences that are recognizable, the largest proportion (90–95%) of the recognizable reads is most similar to genes of bacteriophages in the order *Caudovirales*. A much smaller proportion resembles ssDNA-containing phages and sequences from eukaryotic viruses, primarily those in the families *Phycodnaviridae* and *Mimiviridae*. Since these data are presumed to represent a random sampling, this suggests that the most common DNA-containing viruses in the ocean are viruses that infect bacteria, followed by viruses that infect protists. DNA-containing animal viruses are very rare in the viroplankton, but metagenomic analyses of samples taken directly from marine animals do reveal sequences resembling known animal viruses (Ng *et al.*, 2009; Ng *et al.*, 2011).

The percentage of viral DNA metagenomic sequences that can be reassembled into larger fragments is typically low. Statistical analysis of assembly data suggest that there are many thousands of distinct virus types in a cubic meter of coastal seawater and tens of thousands in a kg of coastal sediment. The shape of the rank-abundance curves for virus sequence types appears to be best described by a power-law function (Hoffmann *et al.*, 2007). Even the most abundant sequence type in these communities is estimated to make up only around 1% (water) or <0.01% (sediment) of the total which illustrates the exceptional diversity of marine viral communities (Edwards and Rohwer, 2005).

RNA-Containing Viruses

The results from analyses of metagenomes prepared from viral RNA have been quite different than those prepared with viral DNA. A larger proportion of the reads (around 50%) are similar to known genes and almost all of them resemble eukaryote-infecting viruses. A small percentage of reads appear to derive from ribosomal RNA from cellular contamination, but none of the sequences resemble any of the known RNA bacteriophages. Most of the reads recognizable as viruses are most similar to sequences deriving from ssRNA-containing viruses in the order *Picornavirales*, but sequences resembling ssRNA viruses in other families outside of that order such as the *Tombusviridae* and dsRNA-containing reoviruses have also been detected (Culley *et al.*, 2006).

Larger percentages of the sequences in RNA viral metagenomes have been assembled than has been the case for DNA metagenomes. In fact, entire genomes have been readily assembled from random reads (Culley *et al.*, 2006, Culley *et al.*, 2007). Although RNA viruses are smaller than DNA genomes on average, the results also suggest that RNA viral diversity in the sea may be lower than that of the DNA viruses. However, there are no reliable estimates yet of just how diverse the RNA virus community might be and few environments have been sampled so far.

Conclusion

Viruses are central to the issue of biodiversity. Whether or not one considers them to be alive, they are nevertheless principal contributors to the diversification of life on the planet through their interactions with every organism in every habitat, and they are exceptionally diverse entities in their own right. As rich and complex as the known virus world is, recent molecular probing of the ocean tells us that we are only skimming the surface of the viral diversity.

Glossary

Archaea One of the two entirely microbial domains of single-celled organisms, evolutionarily distinct from bacteria. Many archaeal characteristics are more similar to eukaryotes than bacteria.

Bacteria An entirely microbial domain of single-celled organisms, evolutionarily distinct from Archaea.

Eukarya A primarily microbial domain of organisms having a membrane-enclosed nucleus and other organelles; includes animals, plants, fungi, and protists.

Fungi Nonphototrophic, heterotrophic eukaryotic microorganisms that contain rigid cell walls; includes mushrooms, molds, and the fungal part of lichens.

Metagenomics The genomic analysis of microorganisms by direct extraction and cloning of community deoxy ribonucleic acid (DNA) from an environmental sample.

Microorganism Single-celled organisms that can only be observed with a microscope, including bacteria, archaea, small eukaryotes, and viruses.

Operational taxonomic unit (OTU) A group of organisms regarded as being distinct from other groups, based on any clearly defined variables.

Polymerase chain reaction (PCR) A method for copying DNA sequences by repeated cycles of synthesis using specific primers and DNA polymerase.

Virus A genetic element containing either DNA or ribonucleic acid (RNA) that replicates in cells but is characterized by having an extracellular state.

Introduction

Although it might not be immediately obvious, our world is a microbial one. Biodiversity is usually discussed in terms of large organisms, but no organisms are more ubiquitous, abundant, or diverse than microorganisms. Microorganisms were the first cellular life forms and were active more than 3 billion years before the appearance of macroorganisms. The metabolic activities that they carried out during this time were critical for creating the conditions for the evolution of multicellular forms. The universal tree of life (Figure 1) emphasizes this point. Multicellular Eukarya (Metazoa, some Fungi, Plantae) are crown groups compared with most microbial Eukarya (e.g., Chromalveolata and Diplomonadida), Bacteria, and Archaea. Microbes force us to stretch our imagination about the limits of metabolic lifestyles, the geography of life, and the roles that organisms play in our lives.

Before the development of molecular methods, it was particularly challenging to understand the evolutionary relationships between organisms. It was generally accepted that there were two basic kinds of organisms, prokaryotes and eukaryotes, distinguished by the absence or presence of a membrane-bound nucleus. In the mid-1970s, Woese and colleagues assembled the universal tree of life based on sequence information of small-subunit ribosomal RNA (SSU rRNA). This breakthrough revealed that life consisted of two very distinct microbial domains, the Bacteria and Archaea, which appear to have diverged very early on in evolutionary history, and a third mostly microbial domain, Eukarya, the exact origins of which remain obscure. Archaea and Bacteria share similar morphological characteristics but Archaea

possess several cellular and genetic characteristics that are more similar to eukaryotes and these organisms tend to be more abundant under extreme environments. As a consequence, Bacteria and Archaea often perform quite different roles. For example, photosynthesis is performed by Bacteria, spread across five different clades, and is not found among Archaea, while methanogenesis is restricted to Archaea. Members of these two domains occupy all habitats on Earth.

Characterizing Microbial Diversity

Although delineating species can be challenging for some macroorganisms, defining a microbial species is particularly challenging, in part because of their genetics. For sexual organisms, a species is usually defined as a group of potentially interbreeding organisms. But many microorganisms, bacteria in particular, are asexual. In addition, microorganisms are too small to define by morphological characteristics, as this is usually done by plant and animal taxonomists. Thus, in stark contrast to diversity surveys of large organisms, these microorganisms often focus on variation in their DNA rather than in their phenotype. For instance, bacterial species are defined as a group of strains that share more than 70% of their genome. Operationally, this definition is applied by melting the genomic DNA of two bacteria and measuring the rate at which they reanneal, a rate determined in part by the similarity of the organisms' genomes.

For microbial community studies, the 70% genomic similarity definition is impractical to apply. Instead, researchers

Figure 1 A phylogeny of some fully sequenced organisms showing the relationship between the three Domains. Green section, Archaea; red, Eukaryota; blue, Bacteria. Labels and color shadings indicate various subdivisions. The branch separating Eukaryota and Archaea from Bacteria in this unrooted tree has been shortened for display purposes. Reproduced from Ciccarelli FD, Doerks T, von Mering C, Creevey CJ, Snel B, and Bork P (2006) Toward automatic reconstruction of a highly resolved tree of life. *Science* 311: 1283–1287, with permission from AAAS.

use genetic markers to characterize microbial community composition and define an operational taxonomic unit (OTU). For instance, in studies that sequence the 16S ribosomal DNA (rDNA) of bacteria, a common OTU definition is a group of sequences that are similar by 97%. This definition is based on the rough relationship between 16S rDNA similarity and the 70% genomic similarity definition. Once microbial species, or other taxonomic units, are defined, then the diversity of a microbial community can be measured. In its simplest form, community diversity is the richness (total number of OTUs) and evenness (relative abundance of the OTUs) in a defined area. A full description of microbial diversity, however, includes variation at many levels of biological organization from the alleles at a particular genetic locus to community among habitats.

Culture Techniques

Throughout most of the twentieth century, microbiologists used culturing techniques to characterize the composition of microbial communities. Traditionally, these techniques involve trying to grow microorganisms from environmental samples on artificial media and mimicking natural environmental conditions, such as temperature and light, in a laboratory setting. These traditional cultivation techniques tend to select for fast-growing taxa, and therefore grossly underestimate actual diversity. The techniques are thought to capture generally less than 1% of all bacterial species and therefore provide a biased view of microbial community composition in most environments. In the early twentieth century, however, promising new cultivation techniques

were developed to overcome these deficiencies. For instance, researchers used small diffusion chambers to grow bacterial colonies in a more natural environment and resource regimen. Others have used high-throughput methods to culture novel strains of oceanic bacteria in a low-nutrient media. These newer techniques have allowed microbial biologists to study the ecophysiological properties of organisms that had been previously inaccessible.

Genetic Methodologies

The development of culture-independent methods, based on the genetic characterization of microbial communities, has allowed the detection of nonculturable species and a more detailed description of microbial communities. Because rDNA molecules are found in all organisms and are probably rarely laterally transferred, they have become a standard phylogenetic marker of microorganisms. Pace *et al.* (1986) built on this idea and used the polymerase chain reaction (PCR) to amplify rDNA genes from community DNA in environmental samples. After PCR, the products can then be further assayed to characterize the diversity of the community rDNA genes. Current open-access databases such as GenBank and the Ribosomal Database Project contain thousands of rDNA gene sequences.

Numerous methods can be used to characterize the diversity of PCR-amplified fragments. DNA sequencing provides the most detailed information, but can be expensive. Fingerprinting methods provide an alternative for characterizing microbial community composition. For instance, terminal restriction fragment length polymorphism (T-RFLP), a modification of the conventional RFLP approach, allows the characterization of a community by analyzing the size polymorphisms of PCR-amplified genes that have been cut at precise sequence locations by restriction enzymes. The resulting fragments are separated by gel electrophoresis and produce a banding pattern that can be used as a fingerprint for comparing community composition among samples.

As DNA sequencing has become faster and cheaper, the field of metagenomics has emerged. Metagenomics uses the DNA sequences of fragments of DNA obtained from a natural microbial community to describe the collective diversity of microbial genomes. Shotgun sequencing breaks up an organism's or a community's DNA into a myriad of short fragments that are individually sequenced. These fragments are then computationally ordered based on overlaps in the genetic code and reassembled into larger genomic fragments. For instance, Venter *et al.* (2004) applied this approach to an open ocean environment in the Sargasso Sea. This pilot project detected 150 new species of bacteria and more than 1.2 million new genes. Screening of metagenomic soil libraries has already led to the identification of various novel biomolecules including enzymes and antibiotics. An alternative approach allows the insertion of large continuous sequences of DNA to be incorporated into bacteria to form artificial chromosomes (BACs), which are then sequenced. This latter approach is much more labor-intensive and time consuming, but allows one to see how genes are organized within microbes, which is important information if one is interested in understanding their evolutionary history.

What is Microbial Diversity?

The immense diversity, small size, and clonal nature of most microorganisms explain why quantifying the biodiversity of microorganisms is fundamentally different from quantifying that of macroorganisms. Microorganisms are so abundant and diverse that only a minute fraction of their diversity has been described (Table 1). Currently, it is infeasible to completely quantify the microbial diversity in even a gram of soil or a liter of seawater. However, a number of studies have tried to estimate microbial diversity globally or within particular habitat types.

Bacterial and Archaeal Diversity

The sheer abundance of bacteria makes estimating the number of bacterial taxa difficult. It has been calculated that there are more bacteria on Earth than there are stars in the universe and that most microbial communities harbor 10^{10} – 10^{17} bacterial cells that compose greater than 107 different taxonomic groups and innumerable functional groups. The magnitude of bacterial diversity is still a matter of debate and perhaps even beyond practical calculation. Dykhuizen (1998) has speculated that there could be 10 billion species of bacteria on Earth. It has only recently been demonstrated that different habitats harbor different amounts of prokaryotic diversity (Figure 2). For instance, Torsvik *et al.* (2002) used DNA–DNA reassociation methods to quantify the total genomic diversity in different communities. They estimate that a few grams of soil or sediment contain thousands of bacterial and archaeal “species.” In comparison, aquatic environments appear to support fewer bacterial taxa (Torsvik *et al.*, 2002).

Because of their high taxonomic and evolutionary diversity, bacteria are incredibly functionally diverse. Bacteria have a striking variety of modes of energy conversion, many unique metabolic pathways, and can utilize a wide range of substrates. Bacteria can oxidize and reduce inorganic sulfur and can assimilate atmospheric nitrogen. Many bacteria have an anaerobic energy metabolism and are often the only organisms living in anoxic environments. Bacteria can even degrade xenobiotic compounds, such as herbicides and pesticides, which are toxic to other organisms.

Because archaea require particular effort to culture, the diversity of this group is historically less well understood than

Table 1 Comparison of the total number of species currently described and the number of species predicted to exist. The term “species” is used loosely as it must be defined differently across taxa

Group	Number of “species”		
	Described	Estimated	% Described
Eukaryotes	1.8×10^6	12×10^6	15.0
Fungi	$7.2\text{--}10 \times 10^4$	1.5×10^6	5.3
Archaea	217		
Bacteria	5007	$4.5\text{--}1000 \times 10^6$	0.1
Viruses	4000	1.0×10^8	0.004

Figure 2 Prokaryotic diversity (genome equivalents) estimated from the reassociation rate of DNA isolated from various habitats. Estimates for pasture soil and arable soil are averages.

bacteria. Molecular phylogenetic surveys, more commonly applied to the study of bacterial communities, are now more frequently being used to characterize the genetic diversity and ecological significance of archaea in a variety of environments including hot springs, deep-sea hydrothermal vents, and coastal waters. A couple hundred archaeal “species” have been described compared with approximately 5000 bacterial “species,” and we lack estimates of how diverse these prokaryotes might be.

Archaea have typically been found living at physical or chemical extremes such as high temperature, high salinity, or strictly anaerobic environments and are immensely physiologically and metabolically diverse. Methanogenic archaea, which occupy anaerobic habitats such as sediments, marshes, and hydrothermal vents, produce methane as a by-product of their metabolism, a process restricted to this domain. Recently, archaea have been found in more benign marine, freshwater, and soil environments. For example, it has generally been assumed that specialist bacteria, which convert ammonia into nitrate, a key step in nitrification, are the main ammonia oxidizers in soil. However, it has been recently suggested that archaea may be the most abundant ammonia oxidizers in both pristine and agricultural soils.

Microbial Eukaryotic Diversity

Molecular methodologies that have revolutionized the understanding of bacterial and archaeal diversity have only recently been adapted to study eukaryotic diversity. Perhaps not surprisingly, molecular surveys suggest that morphological characteristics may conceal a large amount of eukaryotic diversity. For example, *Slapeta et al. (2005)* analyzed the rDNA genes of protists in two ponds and found high within-morphotype diversity. In addition, they detected a number of sequences very divergent from known protist species, implying that the description of global protist diversity is far from complete. Others argue that while local microbial eukaryotic diversity is high, global diversity may be relatively low. They document that many free-living protists (as defined by morphology) are cosmopolitan and suggest that nearly all free-living ciliates have already been discovered.

Like protists, fungal species have been traditionally defined morphologically. *Hawksworth (1991)* suggests that there are at least 1.5 million fungal species globally. Somewhere between 72,000 and 100,000 fungal species have been described, suggesting that as little as 5% of fungal diversity has been discovered. Moreover, with the application of genetic methods such as those applied to bacteria and archaea, estimates of global fungal diversity will likely increase substantially. For example, scientists surveyed the genetic diversity of fungi in the roots of one grass species and found 49 different fungal OTUs, only seven of which were similar to known DNA sequences, and only 6% of which have known ecological roles.

Viral Diversity

Given the remarkable diversity of Bacteria, Archaea, and Microbial eukaryotes, it is perhaps not surprising that the viruses that infect them appear to be similarly abundant and diverse. Viral abundance is estimated to be of the order of 10^{31} , the majority of which infect bacteria and archaea. One kilogram of marine sediment may harbor a million different viral genotypes, and 200 l of seawater contain more than 5000 viral genotypes. In general, viral abundance is well correlated with bacterial abundance, and in fact, bacteriophages are estimated to infect and kill between 4% and 50% of bacteria produced daily in aquatic environments. How, or even whether, viral diversity varies by habitat type is unclear. Researchers have reviewed the extent and distribution of viral diversity in marine habitats and proposed that viruses are highly diverse on a local scale but that this diversity does not vary much over space. In other words, local viral diversity may be representative of global viral diversity.

Maintenance of Microbial Diversity

Ecologists have long been motivated to understand the factors that influence the extraordinary diversity of life on Earth. However, despite the extent of microbial diversity, most of what we know about the maintenance of diversity is based on studies of plants and animals. For example, *Hutchinson (1961)* observed two species of water-bugs in a homogenous aquatic environment and wondered how they could coexist if they both use similar nutrient resources; the same is true about the thousands of microbial taxa that coexist in all habitats. Although a synthetic view of microbial diversity might not be possible, it is useful to consider whether universal patterns and processes govern the diversity of all organisms, large and small.

From an evolutionary perspective, high microbial diversity is created because the rate of diversification exceeds the rate of extinction. If laboratory studies are indicative, the potential for rapid diversification seems greater in microorganisms than macroorganisms. Bacteria and Archaea, in particular, have several traits that make rapid speciation likely. Because they exist in large populations and have rapid growth rates, they have the capacity to accumulate large numbers of novel mutations, which can generate substantial genetic variation. They can also readily take up DNA and get rid of extraneous DNA. Gene transfer and recombination may also accelerate

diversification further. Less is known about the extinction rates of microbes relative to larger organisms; however, many researchers have posited that extinction rates of microbial taxa may be low because many microorganisms have large population sizes and have an ability to survive in a range of environments and tolerate harsh conditions.

From an ecological perspective, once this diversity is created, the question remains how this incredible evolutionary diversity coexists in contemporary communities. Some have reviewed ecological factors, known to be of importance to plant and animal communities, which may also influence the diversity of microorganisms. Below, the authors discuss four of these factors (environmental heterogeneity, disturbance, productivity, and dispersal), and review recent studies that test whether these factors are important for environmental microbial communities.

Environmental Heterogeneity

Among large organisms, species diversity increases with the heterogeneity of habitat types available. For instance, bird species diversity increases with foliage height diversity and mite diversity increases with the number of habitat types in soil subhorizons. Both laboratory and field studies support the hypothesis that increased environmental heterogeneity also increases bacterial diversity. For example, spatial isolation in the soil matrix, created by low moisture content, plays an important role in determining community composition. Zhou *et al.* (2002) observed that soils saturated with water had fewer bacterial taxa and a less even distribution of taxa than patchy, unsaturated soils. Additionally, researchers found that bacterial diversity increased significantly by adding flow heterogeneity in stream mesocosms. Treves *et al.* (2003) examined the competitive dynamics of two species growing on a single resource in a uniform sand matrix under varied moisture content. One species dominated the community under saturated conditions, which were also highly connected, suggesting that these conditions allow competitive interactions to structure the community. As moisture content and connectivity decreased, the less-competitive species became established in the community. Finally, another study similarly found that litter bags with a mixture of species litter contained a more diverse bacterial and fungal community than litter bags with only a single type of species.

Disturbance

Most communities are subject to different types of disturbances that vary in both frequency and intensity. Events that disrupt the physical environment or alter resource and substrate availability are known to influence plant and animal community diversity. Across a wide range of taxa, including corals, butterflies, plankton, and tropical trees, diversity peaks at intermediate intensities or frequencies of small-scale disturbances. For example, algal diversity on intertidal boulders is highest when waves overturn the boulders, exposing new substrate for colonization.

It is difficult to test whether the intermediate disturbance hypothesis explains patterns of microbial diversity in the wild because disturbance is typically confounded with other factors

such as plant cover or soil structure. Field and laboratory studies that have examined the relationship between disturbance and bacterial diversity have generally found that the intermediate disturbance hypothesis holds. For example, Bruce *et al.* (1995) examined the diversity of mercury-resistance genes in sediment-associated bacteria at sites with varying levels of mercury contamination. Consistent with predictions of the intermediate disturbance hypothesis, sites exposed to intermediate levels of mercury had the highest genetic diversity and both pristine and heavily contaminated sites had low diversity. However, other studies have found that disturbance events always result in decreased diversity. For example, Walsh *et al.* (2005) compared archaeal 16S rRNA gene diversity along a salinity gradient prone to high-salinity fluctuations. Heavy-rainfall events impose local high mortality of haloarchaea, and this disturbance regime appears to promote archaeal diversity. Similarly, another study found that the richness of bacterial communities decreased when exposed to low and high doses of the pollutant pentachlorophenol (PCP). Thus, the effect of a disturbance on a microbial community's diversity appears dependent on the type of disturbance as well as the original microbial community.

Productivity

Productivity, the rate at which energy flows through an ecosystem, has long been considered a primary determinant of both plant and animal diversity. A current ecological paradigm is that peak diversity occurs at intermediate levels of productivity, even though this relationship appears to be scale-dependent.

A number of studies consider the relationship between primary productivity and microbial diversity. Productivity appears to be related to microbial diversity; in some instances, these patterns resemble those of plants and animals. For example, Kassen *et al.* (2000) grew cultures of the bacterium *Pseudomonas fluorescens* over a wide range of nutrient concentrations and found that diversity peaked at intermediate productivities. However, another study surveyed two lagoons with different levels of primary productivity and found a greater number of unique bacterial rRNA gene sequences in the more productive lagoon, suggesting that bacterial taxonomic richness increases with productivity. Finally, Horner-Devine *et al.* (2003) estimated bacterial taxonomic richness along a primary productivity gradient in freshwater mesocosms. Although overall bacterial richness was not significantly related to productivity, productivity did influence the richness of separate taxonomic groups. For example, some bacterial groups exhibited a significant hump-shaped relationship with productivity while other groups, such as the α -Proteobacteria, exhibited a U-shaped relationship with primary productivity. Thus, the relationship between ecosystem productivity and microbial diversity appears to be complex and may vary widely across environments.

Dispersal

The small size and high abundance of microorganisms have led microbiologists to generalize that microbial dispersal rates to new habitats is very high, overwhelming spatial differences in taxon abundance. For example, Schauer *et al.*

(2010) examined the bacterial communities in three oceanic basins of the eastern South Atlantic Ocean that were all separated by the Walvis Ridge, a large physical barrier. They found the microbial communities were highly conserved across sites, suggesting a high dispersal capability, despite the physical barrier. However, debate over this view still exists, as other studies demonstrate large biogeographic differences among microbial communities. This evidence suggests that microbial diversity might be influenced by dispersal and isolation patterns. Based on this theory, it has been argued that local bacterial community composition is in part a product of stochastic dispersal events, rather than solely niche differentiation among taxa. The importance of dispersal relative to other factors influencing microbial diversity requires further investigation.

Importance for Ecosystems

Microorganisms are the drivers of key ecosystem processes, including decomposition, nutrient mineralization, and trace gas emission and consumption. Microorganisms are intimately involved in critical pathways of biogeochemical cycles and are the major pathways by which some elemental forms are regenerated to be used by other organisms.

For instance, microbes have a central role in almost all aspects of the nitrogen cycle. Nitrogen fixation is the process by which atmospheric nitrogen is converted into ammonia, which is quickly ionized to ammonium, a form of nitrogen usable by plants. This process, carried out by nitrogen-fixing bacteria, is essential for maintaining soil fertility and agricultural productivity.

If an entire functional group, such as the nitrogen-fixing bacteria, were removed from an ecosystem, the resulting changes would dramatically alter resource supply, processing rates, and plant productivity. However, below this broad functional group classification, it remains unclear whether microbial diversity matters for ecosystem processes. Recently, numerous studies have highlighted the incredible “micro-diversity” of bacteria in some habitats. For example, *Acinas et al. (2004)* sampled 16S rDNA sequences from a coastal bacterioplankton community. They found 516 unique sequences, 50% of which fell into clusters containing less than 1% sequence divergence. Thus, one current avenue of research is to understand whether this type of fine-scale diversity or other levels of diversity have consequences for ecosystem processes.

Microorganisms and Global Change

Terrestrial and Marine Ecosystems

The composition of microbial communities is known to vary with land-use type, temperature, agricultural growing practices, nutrient status, pollutants, and other environmental variables associated with global change. Additionally, there is some evidence that certain properties associated with entire microbial communities can be altered by global changes, such as total microbial biomass, rates of respiration, and

biogeochemical transformations. Little is known, however, how anthropogenic impacts associated with global change will impact microbial communities, and how those changes will ultimately affect ecosystem functioning.

Several studies have examined the links between microbial composition and terrestrial ecosystem functioning and support the hypothesis that global changes will have important consequences for microbially mediated ecosystem processes. *Horz et al. (2004)* considered the impact of multiple global changes on the community composition of ammonia-oxidizing bacteria (AOB) in a California grassland. The authors observed changes in the community structure and abundance of free-living soil bacteria to simultaneous increases in atmospheric CO₂, precipitation, temperature, and nitrogen deposition. The response of AOB was similar to the observed plant responses: Composition and abundance was altered by nitrogen, total abundance decreased in response to elevated CO₂, and both strongly interacted with temperature and precipitation. In contrast, methane-oxidizing bacteria showed a unique response to increased precipitation and temperature; the relative abundance of common methanotroph clades increased in response to both variables, while novel clades had varied responses. Two of the novel clades did not respond to these environmental changes, while one novel clade increased in relative abundance to increased temperature and precipitation.

Further, studies of feedbacks between microbial and plant communities illustrate the potentially unpredictable nature of ecosystem responses to global change. In a one-year factorial field experiment, researchers tested the influence of decreased plant diversity, elevated CO₂ levels, and increased nitrogen deposition on the severity of disease caused by fungal pathogens in a diverse grassland community. All three treatments substantially increased disease severity in the plant community. Because pathogen loads also affect grassland ecosystem processes, this result suggests a route in which microbes respond to climate change and simultaneously feedback and affect climate change as well. Mycorrhizal fungi may also serve as a feedback to the climate system under increased atmospheric CO₂, because they sequester increased amounts of carbon in living, dead, and residual hyphal biomass. In contrast, nitrogen deposition may increase turnover rates of fungal tissue and negate CO₂ effects on fungal biomass.

In marine systems, examination of the impact of global change on microbial communities has only recently begun. Global change is anticipated to impact the physical marine environment in a variety of ways, including temperature increases, shifts in wind and radiation regimes, changes in the frequency of episodic extreme events (such as storms), and acidification. These changes will likely deeply affect the structure and functioning of marine ecosystems, including marine microbial food webs. Recent evidence suggests that global changes, including rising water temperatures, will have dramatic effects on marine microbial systems. For example, *Hoppe et al. (2008)* conducted a mesocosm experiment to examine the effects temperature increases would have on marine microbial communities. When seawater was warmed by 2, 4, and 6 °C, the authors reported an acceleration of bacterial degradation of organic matter derived from a

phytoplankton spring bloom, as well as increased respiration rates. Similarly, others incubated samples in microcosms at different temperatures over short periods of time (24–48 h), and measured the different variables of interest throughout a seasonal cycle in a coastal Mediterranean site. In this study, the warmed samples had on average 20% higher total bacterial carbon demand than unwarmed samples, suggesting a positive feedback loop between warming of coastal waters and CO₂ production.

Overall, predicting the impact of future global change on ecosystems will require a much greater understanding of the response of microorganisms to a variety of environmental variables. Additional research needs to be conducted in both terrestrial and marine ecosystems. Finally, linking the marine and terrestrial components together will require knowledge of the feedbacks that microorganisms will have back on their environment.

Microbial Diseases

The relationship between emerging microbial diseases and global change is a topic of great concern. Many pathogens of terrestrial and marine taxa are sensitive to temperature, rainfall, and humidity. Therefore, global change has the potential to alter the risk of disease through changes in pathogen development and survival rates, disease transmission, and host susceptibility.

So far, evidence suggests that global change will influence a variety of plant, wildlife, and human diseases. For example, several plant diseases are more severe after mild winters or during warmer temperatures, which implies that directional climate warming will alter plant disease severity through longer growing seasons and accelerated pathogen development. Additionally, Kushmaro *et al.* (1998) showed that the bacterium *Vibrio shiloi*, a marine pathogen that infects and causes the bleaching of the coral *Oculina patagonica*, grows well at temperatures close to or exceeding probable host optima.

Research suggests that the most severe and least predictable disease outbreaks might occur if global change alters host or pathogen geographic ranges, resulting in the convergence of formerly separated species and populations. Vector-borne diseases are likely to be the strongest candidates for altered abundance and geographic range shifts because rising temperatures seem to affect vector distribution, parasite development, and transmission rates. Vector-borne diseases of livestock, particularly African horse sickness and bluetongue viruses, recently expanded their ranges. Additionally, vector-borne human pathogens such as malaria, African trypanosomiasis, Lyme disease, tick-borne encephalitis, yellow fever, and dengue have increased in incidence or geographic range in recent decades. Most of these diseases have expanded into regions of higher latitude, in each case accompanied by apparent expansion in the ranges of mosquito, tick, and midge vectors. Research to determine whether these expansions are due primarily to global change or other anthropogenic factors is still ongoing, as well as predicting future distributional changes in disease prevalence.

Although associations between climate and disease do not necessarily imply causation, results from correlational studies and short-term experiments help scientists separate the effects of climate and other components of global change. Overall, further research must be done to improve the ability to predict impacts of global change on microbial diseases.

Glossary

Clone A population of cells all descended from a single cell; a number of copies of a DNA fragment obtained by allowing the DNA fragment to be replicated by a phage or plasmid.

Fingerprint A pattern produced by DNA fragments or lipids that represents a community or species.

Function A process carried out by an organism or group of organisms.

Genotypic Relating to the genetic composition of an organism.

Oligonucleotide A short, single-stranded nucleic acid molecule either obtained from an organism or synthesized chemically.

Phenotypic Relating to observable characteristics of an organism.

Phylogeny The ordering of species into taxonomic groups based on evolutionary relationships.

Polymerase chain reaction A method for amplifying DNA *in vitro* involving the use of oligonucleotide primers complementary to nucleotide sequences in a target gene and replication of the target sequences by the action of DNA polymerases.

Pure culture An organism growing in the absence of all other organisms.

Species A collection of closely related strains.

Strain A population of cells all descended from a single cell.

Introduction

Microorganisms encompass an extraordinary diversity, in both their taxonomy and their ecological functions. As a group, microorganisms range in size over several orders of magnitude, span the three taxonomic domains (Archaea, Bacteria, and Eukarya), and are uniquely capable of performing all known biochemical transformations. The existence of such an immense variety of organisms, combined with the fact that microorganisms are too small to see without magnification, makes the task of measuring microbial biodiversity challenging and even daunting.

Measuring the biodiversity of microbial communities is important for immediately practical and more fundamental considerations. Understanding microbial biodiversity may translate into benefits for biotechnology; management of agricultural, forest, and natural ecosystems; biodegradation of pollutants; reclamation of damaged lands; waste treatment systems; and biological control systems. On a more basic level, microbial processes underlie many essential processes shared by all ecosystems. However, because of our current minimal understanding of these groups of organisms, microbial communities are treated as black boxes in most studies of community, ecosystem, and landscape ecology. Increased knowledge of microbial biodiversity would clarify the details of many ecosystem processes and help generate the baseline information needed to predict and perhaps ameliorate the effects of global climate change.

This article discusses major issues involved in measuring microbial biodiversity and provides an overview of methods for measuring microbial diversity in natural, managed, and engineered ecosystems. The content is intended for biologists and ecologists who desire to incorporate the often-neglected microbial taxa into surveys of biodiversity.

Biodiversity of Microorganisms

The unit of measurement used in biodiversity studies of macroscopic organisms is usually a taxonomic one: the species. Microbial taxonomy has undergone enormous changes in the past two decades. Traditionally in microbiology, a species was phenotypically characterized with organisms classified into taxonomic groups based on morphology, physiology, and metabolism. Recently, however, phenotypic classification has been replaced or supplemented by the use of genotypic analysis. Nucleic acid sequence information derived from the small subunit of the ribosome (16S ribosomal RNA (rRNA) for prokaryotes or 18S rRNA for eukaryotes) is used to determine the degree of similarity among groups of organisms and the evolutionary relationships of microorganisms and all other life-forms. Certain analytical methods use the DNA sequence that codes for the rRNA rather than the rRNA sequence itself. The term used to describe this DNA is ribosomal DNA (rDNA). Although genetic sequencing for individual microbes is labor-intensive, particularly when characterizing complex microbial systems, some microbial ecologists maintain that an in-depth understanding of recently described systems is not possible until this information is gathered.

Far more species of bacteria, fungi, and other microorganisms exist than have been described to date. For example, between 300,000 and 1 million species of bacteria are estimated to exist based on initial in-depth phylogenetic surveys of several specific ecosystems and on calculations based on the reannealing kinetics of DNA extracted from natural environments. In contrast, only approximately 3800 species have been isolated and described by culture-based analyses. As genetic sequence analyses progress, libraries of small subunit rRNA sequences from specific ecosystems are created and compared to sequences in the existing database of known

species. Often, these new sequences exhibit a low degree of similarity compared with the sequences of known species.

Background on Measuring Microbial Biodiversity

Although measuring the biodiversity of animal and plant communities involves counting and identifying individual species, such an approach is neither practical nor feasible for microorganisms. Though individual microorganisms can be counted using microscopy, their morphologies do not reflect their diversity. Visualization reveals little that is defining about identity beyond the observations that an individual cell is a fungus or bacterium, is a particular shape (rod or coccus), or has certain cell wall properties (gram positive or gram negative). Furthermore, counting is often hindered by interference from the physical environment in which microorganisms live. Some of the traits used as classification criteria for microorganisms are relatively plastic and, given that horizontal gene transfer appears common among microorganisms, using phenotypic information to classify species in microbiology is problematic. Additionally, the end point of many methodologies used to characterize microorganisms is not species identification. Thus, extrapolating the concept of species used in classifying large eukaryotes (plants and animals) to microorganisms is questionable.

Another important issue in exploring microbial diversity is the question of whether taxonomic (e.g., species or family groups present) or functional (e.g., types of processes present) diversity is of interest. Some important microbial processes include the transformation of elements in biogeochemical cycles, decomposition of organic residues, biodegradation of pollutants, fluxes of gases to and from the atmosphere, symbiotic relations with plants, and parasitism of other organisms. In ecological studies, the processes carried out by microorganisms within an ecosystem may be of greater relevance than knowledge of the specific identities of organisms involved. A considerable amount of functional redundancy among microorganisms is thought to exist in most communities based on the fact that there are far more taxa than processes. To date, specific functions have been difficult to measure and interpret, especially by nonmicrobiologists, in studies of ecosystem biodiversity. However, with the development of rapid molecular assays, measuring microbial community compositions has become more feasible, and taxonomic characterization is more widely used. Compiling functional and taxonomic diversity measurements is important given that the ecological roles played by organisms represented by newly discovered *ssrDNA* sequences are often unknown.

Numerous methods are available for characterizing microbial communities. Determining which approaches to use is a critical step and depends on the objectives of the study. Should the diversity of a community be measured by characterizing its individual members, a task perhaps too large to be feasible, or by directly characterizing the community as a whole? If taxonomic diversity is of concern, what level of resolution is needed? Given that microorganisms are so small,

what is the appropriate physical scale on which to sample in a study of biodiversity? These points are discussed later.

Enrichment/Isolation versus Direct Measurement of Microbial Communities

Early studies of microbial diversity involved culturing of bacterial isolates on enrichment media supporting their growth ("culture-based") followed by phenotypic characterization of these isolates based on their morphology, physiology, and specific metabolic capabilities. As the tools of molecular biology began to be applied to microbial ecology, it became evident that culture-based methods were failing to detect large portions of microbial communities (no more than 0.1–5% of bacteria in communities are detected using culture-based techniques). Rapidly growing strains of microorganisms were often favored over other members of the community. A culture-based approach therefore probably offers a skewed perspective of microbial diversity in many environments. Consequently, there has been a shift in studies of microbial diversity toward the use of molecular biology and other biochemical and molecular tools that do not require culturing of organisms. Characterization of taxonomic and functional diversity is conducted using information provided by nucleic acids, lipids, and other cellular constituents. If culture conditions of a microorganism are known, data are gathered after individual strains have been separated from a community using enrichment and isolation techniques. In other cases, especially in soils and sediments, biochemical constituents may be directly extracted from the environmental samples, bypassing the isolation step. Many of these methods are currently under development and new ones are being developed at a rapid pace. Those seriously engaged in studies of microbial diversity have to keep close tabs on emerging trends in the field.

Newer methods may introduce their own biases in the assessment of microbial biodiversity, although these biases are presumably not as severe as the culturing bias. For example, molecular methods often make use of the polymerase chain reaction (PCR), during which original copies of specific DNA sequence are amplified exponentially. Two important considerations are that amplification efficiency varies among DNA sequences and therefore PCR results are rarely considered to be quantitative, and that a DNA sequence with low amplification efficiency could conceivably be prominent in the environment but not appear in PCR-based diversity measurements (*see Nucleic Acids*).

These direct measurement techniques may also be used to amplify sequences of rRNA or messenger RNA (mRNA) in order to shed light on the distributions, relative activities, and gene expression (functions) of specific groups.

Level of Taxonomic Resolution

When measuring microbial taxonomic diversity, a decision must be made about the level of taxonomic resolution (e.g., species, genus, family, order, and domain) needed to sufficiently assess diversity. The very definition of species in microbiology is subject to intense debate. Though counting

numbers of individual species can be relatively straightforward in studies of plants and animals, this approach is not feasible for microorganisms. There is an overwhelming amount of diversity among microorganisms and categorizing all types is beyond the scope and resources of most projects. In some cases, determining families, or even kingdoms, within a previously uncharacterized community or ecosystem provides novel and valuable information.

For instance, the DNA from microbial communities as a whole may be presented in the form of a “fingerprint,” which provides a means to classify and describe systems. DNA fingerprints are an abstraction of the original genetic information, but they may be an efficient way to characterize complex microbial habitats in which there is little information linking community structure and community function. They also offer the means to generate hypotheses, test responses of systems to environmental changes and variables, and detect shifts in microbial communities. Efforts may be concentrated on conducting sequence analysis on changing elements of a DNA fingerprint rather than on sequencing all the members of a microbial community.

Environmental Heterogeneity

Obtaining a representative sample of the microbial diversity of a particular environment may be very difficult. It is obvious that most environments are heterogeneous at the spatial and temporal scale of humans. This heterogeneity is even more pronounced at the scale of microorganisms, often in ways that are not immediately evident to humans. For example, microbial communities within the root zone of plants, in which available carbon is high and soil chemistry has been altered, differ substantially from immediately adjacent communities in unrooted soil. These different communities are often only millimeters apart from one another. Also, a community that temporarily forms in a pocket of decaying plant or animal matter may be strikingly different from a community only several centimeters away. Within sediments, communities change substantially with depth as a function of oxygen availability and carbon distribution. This concept is also applicable on the scale of individual soil aggregates. In assessing biodiversity, one approach is to identify important microenvironments within the ecosystem of interest and measure diversity within each major type of microenvironment. With this approach, the number of samples obtained may soon become overwhelming. Another approach is to combine samples from different microenvironments in an attempt to understand the heterogeneity within the entire ecosystem, in which case it may be difficult to interpret factors governing the diversity. An understanding of the underlying physical structure of an environment is a prerequisite to a good sampling design.

Methods for Measuring Microbial Diversity

Far more methods for measuring microbial diversity exist than can be presented here. The methods described here are commonly used and, in composite, represent the breadth of

approaches available. Methods can be divided into those that involve the counting of cells, measurement of cellular constituents, or determination of activity. Most methods provide either taxonomic or functional information about communities, whereas only a few (e.g., nucleic acid-based methods) have the potential to integrate both types of information. The following methods were originally developed in pioneering studies of bacteria, but most are also suitable for studies of fungi and other eukaryotes. Commonly, studies of fungal diversity involve isolation and characterization of strains rather than being community-based. Increasingly, community-based molecular methods are being used for eukaryotic microorganisms.

Counting Microorganisms

Since the development of the microscope, microbial population numbers, and to some degree diversity, have been quantified by examining cells under high magnification. Selective growth media, provided either in petri plates or in most probable number (MPN) assays, permit enumeration of culturable organisms that can metabolize specific compounds. Plates and MPN assays thus give potential functional information about a community. Counting organisms by the latter method requires that organisms grow sufficiently to be detectable.

Microscopy

Major microbial groups, such as bacteria and fungi, can be distinguished by their morphologies as observed under a light or fluorescence microscope after staining the cells. The microscope provides a quick but relatively superficial survey of microbial diversity based on the sizes, shapes, and staining properties of microorganisms. The relatively low number of morphotypes among bacteria limits descriptions of diversity. To some extent, fungal diversity can be investigated by examining hyphal and fruiting body structures and spore morphology, if present. Taxonomic resolution can be improved by using dyes tagged with fluorescent monoclonal antibodies specific to groups or strains, which permit selective visualization of members of the group to which the antibody binds. Recently, development of fluorescent *in situ* hybridization (FISH) with specific DNA probes (described later) has made the microscope a powerful and highly quantitative tool for use in studies of diversity. The antibody and DNA tagging methods require initial characterization of the organism or group of interest in order to develop the antibody or probe.

Plate Counts

Plate counts exploit the fact that individual microscopic cells quickly grow into a colony visible to the unaided eye if provided with suitable growth conditions. Microbial diversity has been assessed by culturing microorganisms on solid nutrient media to which substances are added to specifically promote the growth of target organisms and/or inhibit the growth of unwanted groups. For example, media containing complex organic substances combined with a low pH tend to select for fungi instead of bacteria. Colonies that grow on the plates

are counted and may be further differentiated based on their color or other morphological properties. The diversity of culturable microorganisms is estimated by counting the number of different colonies present on agar media inoculated with a dilution series of the microbial community. Diversity measured based on this technique is unlikely to yield comprehensive, ecologically relevant information about the microbial community as a whole. An advantage of using plating techniques is that strains that grow on plates can often be easily isolated, characterized, and identified by traditional methods of microbiology.

MPN Methods

MPNs make use of specifically designed culturing conditions to estimate the number of microorganisms in a community able to carry out specific functions. The MPN medium is designed to select a specific trophic group by providing carbon, energy, nutrients, and environmental conditions needed to support the growth of that group. Thus, iron reducers are selected by providing anaerobic conditions, a carbon source, ferric iron, and other nutrients. A series of dilutions of an environmental sample are inoculated into the MPN medium. Measurements of turbidity, substrate utilization, or product formation confirm cell growth or activity. The number of organisms capable of carrying out the particular function being investigated is estimated from cell counts from the series of dilutions and with standard statistical calculations. MPN estimation of numbers is obviously a culture-dependent method, biased toward those organisms able to grow and compete under laboratory conditions.

Analysis of Cellular Constituents

Nucleic Acids

Methods using information contained in nucleic acids, DNA and RNA, provide the most specific information about an organism and thus potentially the most detailed information about the biodiversity of a microbial community. **Figure 1** provides an overview of nucleic acid-based methods used in studies of microbial biodiversity. Extraction of DNA or RNA from environmental samples is the first challenge in using nucleic acid-based methods. One approach is to first extract cells from environmental samples (usually from aquatic environments) and then extract cellular DNA or perform analyses on cells collected on filters (e.g., using *in situ* hybridization). *In situ* approaches are quantitative because taxonomic information can be correlated with actual cell numbers within the community. The other approach, direct extraction of DNA without first extracting cells, is more commonly employed in complex environmental media such as soil and sediment. Numerous approaches have been developed to overcome extraction problems associated with specific types of environments, such as soils with high clay or humic acid contents. Other methods have been optimized for rapid extraction to accommodate large numbers of samples. There is usually a trade-off between speed of extraction and quality of extracted DNA (e.g., with respect to purity of the DNA). The efficiency of DNA extraction associated with either the direct or indirect method is difficult to estimate and may range from 10 to 99%. Extraction efficiencies associated with different groups of microorganisms differ, which could skew conclusions about a community diversity.

Figure 1 A schematic of commonly used approaches in nucleic acid-based microbial ecology studies (reproduced from Head IM, Saunders JR, and Pickup RW (1998) Microbial evolution, diversity, and ecology: A decade of ribosomal RNA analysis of uncultivated microorganisms. *Microbial Ecol* 35: 1, with permission from Springer).

Figure 2 The polymerase chain reaction is used to amplify portions of double-stranded DNA from mixtures of DNA from environmental samples. Typically, 30 cycles are completed to generate thousands of copies of the sequences of interest (reproduced from Old RW and Primrose SB (1994) *Principles of Gene Manipulation*, 5th ed. Oxford: Blackwell, with permission from Wiley).

Nucleic acid-based approaches can be divided into those that employ PCR and those that do not. The PCR makes multiple copies of a specific fragment of RNA or DNA from a mixed pool of nucleic acid fragments and permits detection of sequences originally present at very low densities (Figure 2). After PCR amplification, fragments are separated in a polymer

gel on the basis of their length or nucleotide composition. Concentrations of the fragments form “bands” in the gel which are visualized by staining. The pattern made by the bands constitutes a “fingerprint” of a community. PCR is also useful for detecting specific strains, species, or phylogenetic groups in environmental samples and, if used this way, requires *a priori* knowledge about sequence variability/conservation in the species or group of interest. The use of primer sets that target evolutionarily conserved regions, such as universal bacterial or fungal primers, circumvents this problem. However, in highly diverse communities, universal primers may amplify so many different nucleic acid sequences that it is not possible to separate them on a gel (e.g., a “smear” may result). Primer sets that target evolutionarily variable regions are useful for differentiating closely related organisms.

PCR amplification efficiencies differ among individual DNA or RNA sequences, introducing PCR bias. This is of particular concern because it is difficult to distinguish artifacts of PCR from true contributions from members of the microbial community. For example, PCR-based diversity measurements may be biased toward populations with sequences most complementary to primers in the PCR reaction mixture. Consequently, the relative intensity of a PCR product band should only be used as a qualitative measure of the relative abundance of that sequence within the community in the absence of carefully constructed studies that address this issue. Recently developed quantitative competitive PCR methods address this issue. Thermocyclers with detectors that quantify PCR products in real time are also now available.

To obtain information about gene expression (protein or enzyme production), microbial ecologists may utilize a variation of PCR called reverse transcriptase-PCR (RT-PCR). Gene expression is associated with enzyme production directed by another type of cellular RNA called mRNA. Messenger RNA constitutes a small percentage of total RNA but contains the genetic code for individual cellular enzymes. With carefully controlled procedures to eliminate the ubiquitous enzymes called ribonucleases that degrade it, mRNA may be isolated from microbes in environmental samples. With the enzyme reverse transcriptase, mRNA is converted to single-stranded DNA. Once the code is in the form of single-stranded DNA, PCR is performed to produce multiple copies of the code for the enzyme for sequence analysis. Future applications of mRNA analysis will provide insight about the functional diversity of microbial communities.

Finally, PCR may be used as a preliminary step in random cloning and sequencing DNA or RNA from environmental samples from which a “library” of DNA sequences (clones) is generated to represent the diversity present within a community.

PCR-independent methods provide the option of obtaining taxonomic or functional information from nucleic acid extracts or even from intact microbial cells. Hybridization methods entail combining complementary strands of nucleic acids. The complementary strands are genomic DNA in the case of solution hybridization. Other hybridization methods utilize short, single strands of DNA or RNA (oligonucleotide probes) complementary to conserved or variable portions of rRNA or genomic DNA. If the sample contains small amounts of target rRNA or DNA, some of these techniques can be used in conjunction with PCR to reach the threshold of detection.

Table 1 Summary of Nucleic Acid Methods*PCR-Dependent Methods*

The polymerase chain reaction amplifies the signal of microbial DNA from environmental samples. PCR enables detection of microbial populations from very small sample sizes and from extreme environments containing unculturable microorganisms.

Denaturing/Thermal Gradient Gel Electrophoresis (D/TGGE)

Small subunit rDNA fragments of the same length are separated based on nucleotide sequence to produce fingerprint patterns. Isolated fragments may be excised and cloned for sequence analysis.

Intergenic Transcribed Spacer (ITS) Analysis

Fragments between the small and large rDNA genes are separated based on length producing fingerprint patterns. Isolated fragments may be excised to differentiate strains by sequence analysis.

Restriction Fragment Length Polymorphism (RFLP)

Small subunit rDNA PCR products are cut into smaller fragments with restriction enzymes and separated based on length to produce patterns that differentiate simple communities or strains.

Cloning and Sequencing

DNA PCR products are inserted in plasmid vectors which are taken up by bacterial cells. The cells are then cloned to generate many copies for sequence analysis and phylogenetic classification.

PCR-Independent Methods

Hybridization techniques have all the specificity of PCR-based techniques, are without PCR bias, and have the additional advantage of a means to quantify microorganisms.

Solution Hybridization

This method takes community double stranded DNA through thermal dissociation and reassociation process to estimate community DNA complexity.

Membrane Hybridization

Group or species-specific probes hybridize with community DNA or RNA immobilized on a membrane to produce estimates of relative abundance.

Fluorescent In-Situ Hybridization (FISH)

Fluorescently labeled group or species-specific probes hybridize with RNA in intact cells. Individual cells may be counted and types of organisms quantified by microscopy.

Oligonucleotide array

Group, species-specific, or functional gene probes are immobilized on a solid support. Hybridization between probes and community DNA is detected by laser technology.

Table 1 provides a summary of nucleic acid methods commonly used in studies of microbial biodiversity.

PCR-Dependent Methods

Denaturing or Thermal Gradient Gel Electrophoresis Gradient gel electrophoresis resolves double-stranded DNA fragments of the same size based on properties defined by their genetic sequence. First, the small subunit rDNA is amplified from microbial community DNA using universal (genetically conserved) or specific (genetically variable) primer sets. PCR products are separated on a gel that contains an increasing chemical gradient of formamide and urea, which differentially denatures or separates the double-stranded DNA fragments. A variant on the method (thermal gradient gel electrophoresis) uses a linearly increasing temperature gradient in the gel, which has an analogous effect on denaturing double-stranded DNA fragments. PCR product fragments of the same size migrate down the gel at a similar speed until a portion of a particular fragment denatures. At that point the migration of the fragment virtually ceases. Individual bands often correspond to individual microbial strains; however, some strains may produce more than one band (if the strain contains more than one ssrDNA sequence).

The result of denaturing or thermal gradient gel electrophoresis (D/TGGE) analysis is a banding pattern that reflects the composition of a microbial community. Statistical analysis involves scoring the bands in the sample as present or absent

for a particular migration location on the gel, performing a similarity index based on band information, and then evaluating the relationships of samples with cluster analysis algorithms that create dendograms. Although D/TGGE patterns have been used directly to determine Shannon–Weaver diversity indexes, the potential for PCR bias necessitates that extreme care be taken in using these banding patterns as the basis for traditional diversity measurements. Often, up to 60 dominant bands can be discerned in a DGGE profile, whereas it is known that thousands of different species may be present in a community. Thus, D/TGGE does not reveal information about the entire community but rather provides a survey of the dominant members in the community (at least those sequences that amplify by PCR). D/TGGE patterns are particularly rich in information since bands in the gel can be analyzed by hybridization methods or excised for cloning and sequencing.

Figure 3 depicts a polyacrylamide gel of a DGGE fingerprint obtained from a bacterial mixed culture grown on the pollutant MTBE (lane 6) or on trypticase soy broth (a rich medium) (lane 7). Also shown on this gel are bands obtained from individual bacterial strains isolated from the mixed culture (lanes 2–5). The organism depicted by the bands in lane 5 is able to biodegrade MTBE.

Intergenic Transcribed Spacer Analysis The final portion of the ssrRNA gene and the beginning of the large subunit ribosomal RNA (lsrRNA) gene contain highly conserved

sequences, and primers can be designed to amplify the intergenic transcribed spacer (ITS) region (also called ribosomal intergenic spacer analysis). The *lsrRNA* gene is located downstream from the small subunit gene. The intergenic spacer region consists of both noncoding and coding regions; coding regions include transfer RNA genes in the case of bacteria (Figure 4) and 5.8S rRNA genes in the case of eukaryotes such as fungi. The noncoding regions are poorly conserved and contain insertions, deletions, and mutations that do not have a direct effect on the fitness of the organism. Using ITS primers that are universal to bacteria or eukaryotes in a PCR reaction with microbial community DNA generates fragments of different lengths and sequences. These complex banding patterns, like D/TGGE patterns, can be interpreted as a measure of the diversity of the microbial community. As with D/TGGE patterns, a single species may be represented by more than one band. In addition, a single species may have more than one length of ITS region, and one band may represent more than one species. Because closely related strains may have similar 16S rDNA sequences but dissimilar ITS sequences, ITS analysis is an effective tool to detect diversity in situations in which D/TGGE cannot.

Figure 3 Inverted image of fluorescently stained polyacrylamide gel showing DNA bands in DGGE fingerprints. Lanes 2–4, various bacterial isolates from mixed culture; lane 5, MTBE-degrading isolate from mixed culture; lane 6, mixed culture grown on MTBE; lane 7, mixed culture grown on trypticase soy medium. Lanes 1 and 8 are DNA markers.

Figure 4 The intergenic transcribed spacer (ITS) region of bacteria contains none, one, two, or more transfer RNA genes between the 16S and 23S ribosomal DNA genes; ITS-PCR products are separated in polyacrylamide gels on the basis of their length.

Figure 5 shows microbial communities from agricultural soils planted with three different crops discriminated by ITS analysis. The fingerprints were generated from PCR amplification of total soil DNA using universal bacterial ITS primers. Different lanes within each crop category represent different replicates or PCR reactions.

Restriction Fragment Length Polymorphism Small subunit rDNA may also be analyzed by restriction enzymes that recognize and cut double-stranded DNA at precise sequence locations. The fragments derived from the procedure are of different sizes and indicate restriction fragment length polymorphisms (RFLPs). In this method, microbial community *ssrDNA* is either amplified and then digested directly or individual strains are first cloned and RFLP analysis is performed on each clone separately. Restriction enzyme digestion of the *ssrDNA* for a single strain typically results in 2–20 DNA fragment lengths, which are separated by gel electrophoresis. The resulting banding pattern is unique and can be used as a fingerprint to distinguish strains or mixtures of organisms from each other. Whole community RFLP fingerprints are extremely complex, resulting in sometimes indecipherable patterns, making this method useful only in systems of low diversity. Cloning the gene first has the advantage of avoiding overly complex community patterns but the disadvantage of limiting investigations due to the additional cost and workload. In terminally labeled RFLP, one of the primers used in amplifying *ssrDNA* is fluorescently labeled for detection in an automated DNA sequencer. As a result, the fingerprint is less complicated than standard RFLP fingerprints because only one of the fragments formed by the restriction enzyme is detected in the analysis.

Sequencing of *ssrDNA* Clone Libraries The most direct method for analysis of *ssrDNA* sequences obtained from environmental samples is to clone and sequence them. In cloning, individual PCR products are integrated into a vector (vehicle for reproduction), such as a bacterial plasmid, so that individual *ssrDNA* sequences can be reproduced and analyzed. Although this has traditionally been a time-consuming approach, the increasing availability of automated DNA sequencers is making direct sequence analysis more rapid and widespread. The sequence data are used to construct phylogenetic trees, which represent the evolutionary relatedness of microbial species present in a given habitat. Figure 6 shows

Figure 5 Bacterial ITS analysis of whole soil DNA extracts from the crops cotton, tomato, or almond. Each bacterial DNA fingerprint is represented by a pattern that may be categorized by band location and relative intensity and then compared to other patterns by clustering algorithms or other statistical methods.

Figure 6 A distance matrix phylogenetic tree constructed to include cloned and sequenced members of a cyanobacterial mat community. The sequences of previously undescribed clones are analyzed and fit with their most closely related relatives in the cluster diagram (reproduced from Weller R, Bateson MM, Heimbuch BK, Kopczynski ED, and Ward DM (1992) Uncultivated cyanobacteria, Chloroflexus-like inhabitants, and Spirochete-like inhabitants of a hot spring microbial mat. *Appl. Environ. Microbiol.* 58: 3964–3969, with permission from ASM.).

phylogenetic affiliations of 16S rDNA sequences of bacterial clones from a hot spring cyanobacterial mat community.

To date, it has been impossible to exhaustively sample a microbial community using this approach. For instance, in diversity studies of soil bacterial communities, if 100 clones are picked for analysis, each sequence may be unique, suggesting that species richness is far greater than 100. The clones are chosen randomly; thus, the fraction of clones represented by a common sequence can be used to estimate the relative predominance of that population in the community. In addition to PCR amplification bias, artifacts produced by selective cloning of some fragments over others must be considered.

PCR-Independent Methods

Solution Hybridization Microbial diversity of an environmental sample may be estimated using solution hybridization (DNA–DNA reannealing kinetics) approaches similar to those used to determine the genetic similarity of two bacterial strains. In this approach, double-stranded DNA is extracted directly from an environmental sample, denatured, and then allowed to reanneal (return to double-stranded form). Reannealing of DNA can be monitored using spectroscopic techniques. The rate at which the environmental DNA strands reanneal can be compared with the rate at which perfectly matched DNA strands reanneal, and the difference gives a measure of the number of different genomes present in the sample. Results of these assays should be interpreted with two potential artifacts in mind. First, contaminants in the samples (i.e., humic acids in soil DNA extracts) can affect DNA reannealing. Second, since the size of a genome affects reannealing kinetics, necessary assumptions about the “average” size of a genome may skew absolute estimates of the number of genomes present. The genetic similarity between two communities is best estimated by labeling extracted DNA from one community and measuring

the amount of label that hybridizes to DNA from the other community and then vice versa.

Membrane Hybridization Specific taxonomic groups can be detected and quantified by Southern blotting with labeled oligonucleotide probes to complementary *ssrDNA* sequences. With this method, the sample is fixed to a membrane, and then through a series of steps the probes are allowed to hybridize to complementary portions of microbial nucleic acids. The probes are either radiolabeled or enzyme linked with fluorescent dyes for quantification by densitometry or fluorimetry. The DNA on a single membrane may be stripped of one probe and then hybridized with others to provide estimates of relative abundance of certain taxa or other phylogenetic information. This technique is more rapid than cloning and sequencing, but the appropriate quantification standards must be used. Precise quantification of the number of individuals per species, however, is not possible by this method because the naturally occurring number of copies of the *ssrDNA* varies among microorganisms. The membrane hybridization technique can also be used with ribosomal RNA, in which case it is called Northern blotting. Northern blots provide quantitative estimates of active taxa because the rRNA concentration is higher in those members of a community that are physiologically active.

Fluorescent In Situ Hybridization FISH is a modification of oligonucleotide probing that allows spatial location of specific populations in their native habitat. With this technique, fluorescently labeled oligonucleotides hybridize to *ssrD*/RNA inside cells and are detected with an epifluorescent or laser confocal microscope. Microorganisms are first pretreated to create gaps in their membranes that permit the labeled oligonucleotides to enter the cells. Group- or species-specific oligonucleotides may be labeled with differently colored fluorescent molecules such that multiple groups of organisms can be observed in a microscopic field. Microscope images can be analyzed automatically to reduce operator errors in identifying and counting fluorescent cells. In soil systems, in which the majority of cells are presumably dormant, FISH results may lead to an underestimation of the microbial diversity due to detection limits. Because this technique allows visualization of individual cells, results are not confounded by variation in the number of *ssrDNA* gene copies among different microorganisms. This method is problematic in soil systems because soil organic matter fluorescence interferes with the probes' fluorescent signals and because probes may bind to soil constituents.

Oligonucleotide Arrays A promising new variation of hybridization analysis involves attaching arrays of oligonucleotides to a solid surface rather than attaching sample DNA to traditional blotting membranes. In this technique, multiple oligonucleotide sequences are immobilized on a glass or plastic slide, and the sample DNA is radioactively or fluorescently labeled. After labeled PCR fragments or rRNA hybridize to complementary oligonucleotides on the slide, the signal is quantified using laser technology. As many as 10,000 different sequences can be deposited on a small microscope slide. Due to variation in hybridization kinetics, the results are not strictly quantitative

but can show trends in population dynamics. An advantage of this technology is that, given sufficient DNA or RNA, it can be used with nucleic acids extracted directly from the environment without an intermediate PCR step. Interpretation of the wealth of data that results from this method remains a formidable challenge. However, it is currently the only technique that can detect thousands of different populations rapidly, and it likely will have a large impact on microbial diversity studies. As more environmental isolates are characterized and sequenced, oligonucleotide arrays will become more useful for studying biodiversity.

Fatty Acid Analysis

In addition to DNA-based identification methods, microorganisms can be classified based on their cellular lipid composition. Lipids can be used to identify individual strains or to characterize whole communities. The most commonly analyzed lipids are the phospholipid fatty acids (PLFAs). PLFAs are the primary component of cell membranes and are present in all living organisms. Fatty acids are distinguished on the basis of chain length, number and location of unsaturations, and location of substituents (e.g., methyls, hydroxyls, and cyclopropane rings).

In lipid analysis of individual strains, cells are grown according to a standard protocol and their cellular fatty acids are extracted. Chromatographic analysis of the fatty acids provides a fingerprint, which is compared to a database to identify species. In a modification of the method, PLFAs derived primarily from the cell membrane are analyzed instead of whole cell fatty acids. Analysis of PLFAs in environmental samples is based on an extraction procedure in which polar lipids are extracted and purified using silicic acid chromatography. The ester-linked fatty acids of bacteria, or ether-linked fatty alcohols of Archaea, are analyzed by capillary gas chromatography or gas chromatography with mass spectrometry (White *et al.*, 1979). Figure 7 shows a correspondence analysis plot of PLFA abundance data for 100 sulfate-reducing bacterial cultures together with uncharacterized sulfate-reducing cultures enriched from sediments in Clear Lake, California. Bacterial strains (represented by points) which lie close together have similar fatty acid compositions.

PLFA analysis is also used to characterize entire microbial communities in environmental samples. There are three ways in which PLFAs can provide information about diversity: (i) The entire PLFA profile can be used as a fingerprint which reflects the composition of the total soil community; (ii) signature fatty acids can be used to detect specific subgroups within the community, e.g., sulfate reducing bacteria, methane oxidizing bacteria, fungi, and actinomycetes; and (iii) certain lipids are physiological indicators of environmental stresses, e.g., the ratio of saturated to unsaturated fatty acids, the ratio of *trans*- to *cis*-monoenoic unsaturated fatty acids, and the proportion of cyclopropyl fatty acids.

Measurement of Process or Function

Substrate Utilization Patterns

The measurement of substrate utilization patterns is commonly used to evaluate functional diversity of bacterial

Figure 7 A diagram summarizing PLFA abundance data for pure cultures of sulfate-reducing bacteria and uncharacterized strains enriched from polluted sediments in Clear Lake, California. A, *Desulfovibrio*; B, *Desulfobacter*; C, *Desulfobulbus*; D, *Desulfotomaculum*; E, *Desulfobacterium*; F, *Desulfomicrobium*; G, *Desulfuromonas*; H, other (see text); I, *Desulfomonas*; J, *Desulfobacterium*; K, *Desulfococcus*; M, *Desulfobotulus*; N, *Desulfosarcina*; O, *Desulfomonile*.

populations. The commercially available Biolog system, which contains 95 carbon and energy sources on one microtiter plate, is widely used because of its convenience. The plate is inoculated directly with a sample of a microbial community (e.g., a dilution of a soil or sediment suspension) and then incubated under aerobic conditions. Substrate utilization leads to the development of a blue color originating from a redox-sensitive dye. Comparison of well color development patterns among different microbial communities coupled with multivariate statistical analysis may yield information on the functional relatedness of the bacterial populations in the sample.

A major drawback of this method is reliance on the activity of culturable organisms; thus, organisms unable to grow under the incubation conditions are not represented. There is also debate regarding the environmental significance of the carbon sources used in the microtiter plates. These carbon substrates were originally chosen for their ability to distinguish pathogenic bacterial isolates from one another, and therefore bear little relation to substrates encountered by microorganisms in their natural environments. In response to this criticism, plates that contain substrates more common in aquatic and terrestrial environments have been developed and used in some recent applications.

Enzyme Assays

A variety of enzymes have evolved to carry out the diverse metabolic processes in which microorganisms are engaged. Six major classes of enzymes have been defined that, in turn, are divided into subclasses on the basis of the type of reactions they catalyze. Table 2 provides an overview of common enzymes found in soil. Enzymes found in the environment may

be associated with cellular cytoplasm or may be attached to the lipid membranes or surfaces of microbial cells. Other enzymes may be present outside of cells, either in solution or attached to particles in the environment. Enzymes are usually measured based on the type and amount of activity they catalyze under controlled conditions in response to added substrates. "Potential" rather than actual activity is commonly measured.

Some enzymes are present in all organisms (protease and hydrogenase) and give general information about the intensity of biological activity in a sample. Other enzymes catalyze more specific reactions and provide information about the diversity of processes that potentially can be carried out by microbial populations within a given environment. These include enzymes associated with decomposition of polysaccharides (e.g., cellulase, chitinase, amidase, and xylanase), the transformation of phosphorus (e.g., specific kinds of phosphatase) and sulfur (e.g., arylsulfatase), lipid metabolism (e.g., lipase), lignin degradation, and the metabolism of specific environmental pollutants.

Computational Needs

Within the past decade, many large data sets describing microbial communities have been generated using the new biochemical approaches described previously. Much of the information potentially available in these data sets is overlooked because biologists often do not employ the statistical approaches necessary for handling such large data sets. Interesting information may be buried in improperly or unanalyzed data; therefore, serious attention must be given to this problem. One challenge is reducing these large data sets to smaller sets of variables or components. In this way, classification tools can be used and models can be constructed to predict the response of microbial processes to changes brought on by human activity or environmental changes.

Standard multivariate techniques are commonly used to explore the "natural" relationships within a data set (principal component analysis and correspondence analysis) and to determine the correlation of environmental variables to specific components (constrained ordination techniques such as canonical correspondence analysis). In addition, regularized discriminant analysis (RDA) and partial least squares (PLS) are used to test the significance of *a priori* knowledge about the data sets (e.g., the significance of environmental variables or sample category). RDA uses a regularized covariance matrix estimate for the conventional statistical discriminant analysis methods. PLS is a multivariate calibration tool and can also be applied as a modeling method to solve pattern classification problems. PLS finds a set of latent variables in the measurement variable space (e.g., lipids or DNA banding patterns or sequences) that have a maximum covariance with the dependent variable space. Variable selection can then be used to choose which variables are most important for modeling. Artificial neural net analysis can be used to explore nonlinear relationships within the data sets, (e.g., relating community composition to process rates). Using these approaches, it may be possible to address such questions as which traits are shared by all members of certain classes

Table 2 Some Enzymes Extracted from Soils and the Reaction They Catalyze

<i>Recommended name</i>	<i>Reaction</i>	<i>Substrate</i>
Oxyreductases		
Catalase	$2\text{H}_2\text{O}_2 \rightarrow \text{O}_2 + 2\text{H}_2\text{O}$	H_2O_2
Peroxidase	$\text{Donor} + \text{H}_2\text{O}_2 \rightarrow \text{oxidized donor} + 2\text{H}_2\text{O}$	H_2O_2 , pyrogallol, chloroanilines, <i>o</i> -dianisidine
Monophenol monooxygenase (polyphenol oxidase)	$\text{Tyrosine} + \text{dihydroxyphenylalanine} + \text{O}_2 \rightarrow$ $\text{dihydroxyphenylalanine} + \text{dioxophenylalanine} + \text{H}_2\text{O}$	<i>d</i> -Catechol, <i>p</i> -quinol, <i>p</i> -cresol, 3,4- dihydroxyphenylalanine, <i>p</i> -phenylenediamine
Hydrolases		
Carboxylesterase	$\text{A carboxylic ester} + \text{H}_2\text{O} \rightarrow \text{an alcohol} + \text{a carboxylic acid anion}$	Malathion, hydroxymethylcoumarin butyrate
Arylesterase	$\text{A phenyl acetate} + \text{H}_2\text{O} \rightarrow \text{a phenol} + \text{acetate}$	Phenyl acetate, phenyl butyrate, naphthyl acetate
Alkaline phosphatase	$\text{Orthophosphoric monoester} + \text{H}_2\text{O} \rightarrow \text{an alcohol} + \text{orthophosphate}$	<i>p</i> -Nitrophenyl phosphate
Acid phosphatase	$\text{Orthophosphoric monoester} + \text{H}_2\text{O} \rightarrow \text{an alcohol} + \text{orthophosphate}$	<i>p</i> -Nitrophenyl phosphate
Arylsulfatase	$\text{A phenol sulfate} + \text{H}_2\text{O} \rightarrow \text{a phenol} + \text{sulfate}$	<i>p</i> -Nitrophenyl sulfate
Cellulase	Endohydrolysis of 1,4- β -glucosidic linkages in cellulose, lichenin, and cereal β -glucose	Cellulose, carboxymethylcellulose
β -Glucosidase	Hydrolysis of terminal, nonreducing β -D-glucose residues with release of β -D-glucose	<i>p</i> -Nitrophenyl- β -D-glucoside, cellobiose, <i>p</i> -nitrophenyl- β -D-glucopyranoside
β -Fructofuranosidase (Invertase)	Hydrolysis of terminal nonreducing β -D-fructofuranoside residues in β -fructofuranosides	Sucrose
Proteinases		
Urease	Hydrolysis of proteins to peptides and amino acids $\text{Urea} + \text{H}_2\text{O} \rightarrow \text{CO}_2 + 2\text{NH}_3$	Casein, gelatin, albumin Urea
Lyases		
Aromatic-L-amino-acid decarboxylase	$\text{L-Tryptophan} \rightarrow \text{tryptamine} + \text{CO}_2$	<i>dl</i> -3,4-Di-hydroxyphenylalanine, <i>dl</i> -tyrosine, <i>dl</i> -tryptophan, <i>dl</i> -phenylalanine, tryptophan

(e.g., communities on a particular land use and vegetation type) and which components of a community are linked to specific processes such as pollutant degradation and nitrogen cycling.

Future Directions

Great care must be taken to not overstate the reliability of microbial diversity measurements currently available. None of the diversity measurements currently available have the ability to (i) exhaustively sample a community, (ii) quantify population densities, and (iii) resolve individual populations. Ecologists who study macroorganisms have the ability to satisfy all three of these criteria and therefore it is difficult to compare the diversity of large organisms with that of microorganisms. It is likely that a large subset of microorganisms exist at low population densities and are dormant. When this fraction of the community encounters environmental conditions suitable for growth, the dormant populations expand, and only then do we have the ability to measure them. Thus, current techniques tend to be biased toward dominant members of a microbial community. Despite this limitation, ecological studies of microorganisms and this limited perspective have already revealed overwhelming biodiversity.

Once the tools are developed to characterize and analyze data describing microbial communities, numerous questions can be considered. Questions of interest may include the following:

1. What environmental gradients (e.g., vegetation, time, soil texture, and topography) are most strongly correlated with the composition of specific communities or patterns of communities in general?
2. What other (e.g., nongradient) factors also regulate community diversity?
3. Do communities undergo succession within a year? How much do communities vary year to year? Are there seasonal patterns common to all communities across biomes?
4. Are there associations between microbial communities (e.g., facilitation, competition, and interaction)?
5. Does human disturbance alter communities to a greater degree and in different ways than do seasonal and vegetation changes, and are there general patterns that are indicative of disturbance?

Glossary

Community composition It is the identity and relative abundances of all taxa in a community.

Cosmopolitan This refers to being present everywhere, globally distributed.

Dispersal limitation It is the inability to move to and/or colonize/establish at some location.

Drift It is the influence of stochastic demographic variability (such as birth, death, and migration rates) on biotic composition in an area.

Historical processes These are the evolutionary and ecological processes that occur in the recent or distant past including immigration, emigration, speciation, extinction, drift, and/or past selection by the environment.

Microorganism or microbe These are bacteria, archaea, protists, fungi, and small metazoans, typically smaller than 0.5 mm in equivalent diameter and with mass $< 10^{-5}$ g; may also include viruses.

Spatial autocorrelation It is the tendency of geographically close observations to be more similar than geographically distant observations.

Stochastic It means a random effect due to chance events.

Taxon A group into which related organisms are classified based on a designated relatedness cutoff, often using sequence similarity of a marker gene; for example, species-equivalent taxa may be defined as at least 99% similar in their 16S rRNA gene sequence.

Taxonomic resolution The level of genetic variation of the taxa considered.

Introduction

Biogeography is the study of the distribution of biodiversity over space and time. It aims to reveal why organisms live where they do, and at what abundance. The study of biogeography offers insights into the ecological and evolutionary mechanisms that generate and maintain diversity, such as speciation, extinction, dispersal, and species interactions. The results of biogeographic studies also have direct application in the modeling of ecosystem responses as they differ between habitats and respond to global change. Since the eighteenth century, biologists have investigated the geographic distribution of plant and animal diversity, leading to important advances in ecological theory. However, until recently, microorganisms have rarely been considered in this regard.

The Baas-Becking Hypothesis

Although few early microbiologists performed biogeographic studies, a central theme in microbial biogeography today is the so-called “Baas-Becking hypothesis,” dating back to almost a century. The hypothesis suggests that for microbial taxa, “everything is everywhere – the environment selects,” (Baas-Becking, 1934). The claim “everything is everywhere” implies that microorganisms are so abundant and have such enormous dispersal capabilities that they can rapidly erase any geographic patterns generated by past evolutionary and ecological events. The claim that “the environment selects” implies that different contemporary environments allow for selective growth of distinctive microbial assemblages. If true, and dispersal and selection are effectively instantaneous, the hypothesis implies two expectations: (1) microbial

communities will vary among habitats but similar habitats in different locations will harbor similar active microbial communities and (2) the lack of dispersal limitation means that “seed” populations of every kind of microbe can be found everywhere, albeit possibly at very low abundance.

In the sections that follow, some of the recently observed microbial distribution patterns are described. A framework is reviewed for testing the Baas-Becking hypothesis as well as three other alternative hypotheses. It is seen that the current literature generally supports the second expectation of the Baas-Becking hypothesis; the environment clearly has a strong effect on microbial composition, as it does for the composition of larger organisms. However, there is also evidence that the first expectation does not always hold; in other words, that some microorganisms may be dispersal limited.

The Molecular Genetic Revolution

For many decades it was not feasible to evaluate the Baas-Becking hypothesis because suitable methodologies for identifying the majority of microbial taxa in an environmental sample were not available. Until the 1980s classical cultivation techniques were necessary for proper identification of bacteria, archaea, and the smallest protists, and such identification, applied to whole communities, would have been onerous. However, some of the first modern studies to describe the large-scale biogeography of microbes did so by employing morphological identification techniques to group eukaryotic microbes (Protista) to the genus or near species levels. These studies found that virtually all species were detected in a range of widespread and varied habitats, suggesting that such microbes were indeed globally distributed and therefore

corroborating the first expectation of the Baas-Becking dictum (Finlay, 2002; Fenchel and Finlay, 2004). In recent years these claims have been challenged (Foissner, 2006), however, with one argument being that morphologically defined microbial species are “cryptic” in that they are not adequate representations of genetically differentiated species.

The application of newly developed molecular methodologies has now allowed microbial biogeography surveys to characterize microbial taxa genetically, thereby avoiding the caveats associated with cultivation-dependent or morphological-based techniques. Such techniques obtain DNA sequences directly from environmental samples without the need for cultivation. Sequences are then classified into microbial taxa, often referred to as operational taxonomic units (OTUs), which are defined by the nucleotide sequence similarity of one or more genomic regions, usually a marker gene such as 16S rRNA. Sequence similarity cutoffs are often arbitrarily chosen to be coarsely analogous to species or genus in larger organisms. However, taxa can be defined at any level of taxonomic resolution, from unique sequences to OTUs that lump together genetically and phenotypically diverse microbes. Thus, as compared to morphological techniques, sequence-based identification generally allows a greater amount of microbial diversity to be distinguished and taxa to be defined with greater resolution.

Indeed, some of the first studies utilizing culture-independent molecular methods revealed that past culture-based studies missed the vast majority of the microbial diversity present in the environment (e.g., Ward *et al.*, 1990). Additionally because these techniques continue to evolve and improve in coverage and depth of sampling, microbial diversity has been sampled much more deeply and widely than ever before (e.g., Sogin *et al.*, 2006). Microbial biogeography has benefited tremendously from these advances, and in fact most of the work presented in this article relies on this approach.

General Patterns in the Distribution of Microbes

Micro- and macroorganisms are often involved in intimate and specific associations that affect each other's geographic distributions. Studies have recognized for many years that host-associated and pathogenic microorganisms exhibit patterns of genetic, morphological, and functional differentiation related to the distribution of their hosts (Hedlund and Staley, 2003). Thus, there is little debate that most host-associated microbes display biogeographic patterns that parallel those of animals and plants.

Debate remains about the extent to which nonhost-associated microbes display biogeographic patterns. Studies from a diversity of habitats, including soils, sediments, hot springs, marine, and freshwaters, show clearly that community composition differs across space and time, as reviewed extensively in recent years (e.g., Foissner, 2006; Martiny *et al.*, 2006; Lindström and Langenheder, 2011). Not only do the distributions of microorganisms appear to be nonrandom, but these distributions are also often similar to those observed for animals and plants.

Certainly, not every study thus far has found evidence for significant biogeographic patterns among the microbial taxon

of interest (e.g., Fenchel and Finlay, 2004). However, the existence of microbial biogeography does not depend on every microbial taxon being nonrandomly distributed. The presence of cosmopolitan microorganisms – the “pigeons” of the microbial world – does not exclude the possibility that other microbial taxa have strikingly uneven geographic distributions. Similarly, microbial communities that contain a large proportion of evenly distributed cosmopolitan taxa can still exhibit biogeographic patterns driven by a minority fraction of taxa that are not evenly abundant everywhere.

The evidence for microbial biogeography is reviewed below by describing some general biogeographic patterns that have been observed for free-living microbes.

Endemism

The existence of endemic microbial taxa would, in theory, be the simplest demonstration that microorganisms are nonrandomly distributed. Endemics are, by definition, restricted to a particular geographic range and therefore are not evenly distributed across the Earth. In practice, however, characterizing the geographic ranges of microbes is difficult. First, because a vast majority of bacterial taxa in a sample are rare (Sogin *et al.*, 2006), many taxa that are present will not be detected. Thus, proving the absence of a microbial taxon within highly diverse natural assemblages is nearly impossible with currently available techniques. Second, it is equally difficult to determine whether observed taxa are actually active in a given sample, and therefore perceiving the location as a suitable habitat. Indeed, many microbes are capable of dormancy stages, and recent evidence suggests that many taxa detected in a location are dormant (Lennon and Jones, 2010), perhaps having arrived there as transient migrants. Thus, without employing a strategy to identify active versus dormant taxa, the actual active habitat range of some microbes might not be distinguishable from a cosmopolitan distribution.

Significant genetic divergence among taxa in different locations is perhaps the strongest evidence for microbial endemism. Many studies employ statistics such as Sewall Wright's F_{ST} or similar metrics, which compare the genetic diversity of a microbial taxon within locations relative to that among all locations combined. Some studies further find that particular microbial clades are restricted to different regions of the world (as demonstrated in Figure 1). For instance, Whitaker *et al.* (2003) showed clear genetic differentiation among hyperthermophilic archaea from geothermal hot springs on different continents. Significant genetic divergence among geographic locations is not just a demonstration that the genetic diversity of microbes varies in space, but it is also evidence that the sampled microbial communities are not completely mixed by dispersal of individuals between them – that is, the communities are isolated from each other due to dispersal limitation.

Latitudinal Gradients

Since the eighteenth century, it has been widely recognized that there is a broad tendency for animals and plants to

Figure 1 Phylogenetic tree depicting the genetic relatedness of hypothetical isolates (indicated by colored circles) collected from similar habitats around the world (inset). Isolates from geographically nearer locations are more closely related than they are to isolates from more distant locations. Similar patterns have been observed with hot spring Archaea, for example, with isolates from locations in North America being more similar to each other than to those from Asia. Inset: Map showing sampled locations. Different colors correspond to the geographic origin of isolates. Scale bar approximates 1 nucleotide substitution per 1000 bases.

exhibit a gradient of higher species richness (i.e., α -diversity) in tropical regions and lower diversity in polar ones. There are numerous nonexclusive explanations of such patterns, but prominent among them is the suggestion that this relationship is driven by latitudinal changes in temperature and/or productivity (Rosenzweig, 1995; Hillebrand, 2004). Some meta-analyses have indicated that the gradient tends to get weaker as animals get smaller, which might be extrapolated to suggest little or no latitudinal richness gradient for bacteria-sized organisms (Hillebrand, 2004). Recent studies of bacterial diversity have begun to look for such patterns. In a study of 98 soil samples from North and South Americas, Fierer and Jackson (2006) reported no relationship between bacterial richness and latitude or temperature, instead finding that soil type, and especially pH (which varied greatly among samples) was an overwhelmingly important factor, with lower diversity in more acidic soils. In contrast, studies of marine planktonic bacteria, living in the seawater environment that is much more chemically and physically uniform than soils, found evidence

of a latitudinal gradient in bacterial richness (Pommier *et al.*, 2007; Fuhrman *et al.*, 2008).

Elevational and Depth Gradients

Scientists have long-recognized elevational gradients in plant and animal community composition. Over relatively short geographic distances, dramatic changes in climate with elevation are often associated with stark biotic turnover in a wide range of taxonomic groups such as birds, trees, and insects. In particular, species richness tends to exhibit either a hump-shaped or monotonically decreasing relationship with elevation. Like with latitudinal gradients, a number of non-exclusive hypotheses have been proposed, but the cause of elevational patterns remains poorly understood. Recent work in the Rocky Mountains showed that bacterial richness decreased monotonically from low to high elevations; while plants from the same system exhibited a unimodal pattern of richness, with richness peaking at midelevations (Bryant *et al.*,

2008). In contrast, bacterial richness in organic soil, mineral soil, and on leaf surfaces along an elevational gradient in the eastern Andes of Peru showed no significant relationship between richness and elevation (Fierer *et al.*, 2011), while bat, bird, and tree richness decreased along the same gradient. Finally, bacterial richness increased monotonically with elevation in a stony stream in China, while diatom richness decreased and macroinvertebrate richness showed a clear unimodal pattern with elevation in the same system (Shen *et al.*, 2011). Overall, these studies suggest that bacteria also vary in composition and richness along elevational gradients, but so far, no consistent patterns have emerged across studies and ecosystems. A similar analysis applies to depth in aquatic and marine systems, which are often physically, chemically, and biologically stratified (layered with depth). Indeed, microbial communities have been known for decades to vary with depth and oceanographic conditions, and even have the potential to be tracers for vertical water movement (e.g., Kriss, 1960). Correspondingly, several studies have demonstrated clear variations of microbial composition with depth (e.g., reviewed by Martiny *et al.*, 2006; Lindström and Langenheder, 2011).

Distance–Decay Relationships

Generally, the similarity between community composition decreases as the distance between two locations increases (Nekola and White, 1999). This so-called distance–decay relationship (Figure 2) indicates not only that communities are different in different locations, but also that this variation is spatially autocorrelated. Multiple factors may act alone or in combination to produce this pattern. First, environmental variables tend to be spatially autocorrelated (as in a cline or gradient) and organisms with differing environmental or

Figure 2 An example of a distance–decay curve. Each point represents a single pairwise comparison of the total number of locations sampled. The solid line represents a negative relationship between community similarity and geographic distance across all points. Using the same hypothetical microbial isolates from Figure 1, the pairwise comparisons from North America would be on the upper left side of the figure (more similar to each other and closer together spatially), and comparisons between North America and Europe or Asia would be in the lower right side.

niche preferences are selected from the available pool of taxa. Second, restricted dispersal of organisms over space can result in geographic isolation or clustering of taxa.

Distance–decay curves have been consistently observed for microorganisms at a range of taxonomic and spatial scales (e.g., Cho and Tiedje, 2000; Green *et al.*, 2004; Horner-Devine *et al.*, 2004; Martiny *et al.*, 2011). For instance, Whitaker *et al.* (2003) showed that not only did archaea diverge among the hot spring locations, but also these differences were spatially autocorrelated. The particular processes underlying these patterns can also vary with taxonomic or spatial scale, as has been shown for bacteria from salt-marsh sediments from around the world (Martiny *et al.*, 2011). Regardless of how the pattern is created, the decline of similarity in communities across space is considered to be powerful evidence of a nonrandom geographic distribution and has been repeatedly observed for microbes in an exhaustive range of habitats and spatial scales.

Taxa–Area Relationships

Closely related to distance–decay patterns are species– (or taxa–) area relationships (Figure 3). Here species are used to refer to any microbial taxon defined by relatedness. A positive relationship between the number of species observed and the size of the area sampled has been observed repeatedly in plants and animals in a wide range of ecosystems for over a hundred years, often ascribed in part to the fact that as area increases, more types of habitats and microenvironments are included (Rosenzweig, 1995). This empirical species–area relationship usually fits a power-law function, $S = cA^z$, where S is the number of species, A is the area sampled, and c is the intercept in log–log space. The species–area exponent, z , is a measure of the rate of change of the slope with increasing area, that is, the rate of turnover of species across space.

It is rarely, if ever, possible to exhaustively sample the microbial diversity in even a small area, let alone in areas of

Figure 3 A taxa–area relationship, showing a linear increase in the number of taxa observed with increasing area sampled, on a log–log scale. S is the taxon richness, A is area, and c and z are constants that differ between taxa and habitats, with c the richness at the smallest scales and z the slope of the line reflecting the rate of increasing richness with increasing area or time. Note that on a log–log scale, the taxa–area relationship is equivalent to $\log(S) = \log(c) + z\log(A)$.

increasing size. However, researchers have used distance–decay curves to determine the taxa–area exponent, z , and have shown that taxa–area relationships also hold in microbial communities (e.g., Green *et al.*, 2004; Horner-Devine *et al.*, 2004). Currently, much microbial biogeographic research focuses on understanding why “ z ,” or the rate of microbial turnover, varies among different taxa, ecosystems, and spatial scales. Such an approach offers an insight into the turnover of community composition across space and how this turnover may vary with the spatial scales sampled. In addition, it is important to consider the spatial scales on which the underlying processes operate and how the relevant scales compare across taxa.

Seasonality and Taxa–Time Relationships

Although most microbial biogeography studies focus on spatial variation, community composition and diversity can also vary nonrandomly over time. For instance, many studies observe very strong temporal and seasonal dynamics in bacterial community composition. Fuhrman *et al.* (2006) showed robust, repeatable temporal patterns in the community composition for bacterioplankton off the coast of Southern California. Similarly, near-surface ocean bacterioplankton in the English Channel exhibited strong repeatable seasonal patterns with peaks in richness during the winter (Gilbert *et al.*, 2009).

As for area, the number of species observed also increases with the time span over which the community is observed (i.e., a positive species–time relationship) due to immigration and also inclusion of more varied conditions. Although less well studied than the taxa–area relationship, organisms from a range of taxonomic groups and ecosystems types exhibit significant and similar taxa–time relationships within and across years (White *et al.*, 2006). Recent work in the Mid-Atlantic Bight showed that time rather than space or measured environmental variables was the primary driver of microbial community composition (Nelson *et al.*, 2008). Bacterial taxa–time relationships have also been observed in terrestrial environments (e.g., Redford and Fierer, 2009).

Interpreting Microbial Biogeographic Patterns

The patterns discussed above (see General Patterns in Microbial Distribution) indicate that not all microbial taxa are randomly distributed and show that at least some, if not most, microbes exhibit biogeographic patterns. Indeed, recent advances have been made to describe the existence of such nonrandom patterns in a wide variety of microbial taxa from a broad range of habitat types, as has been reviewed previously (Foissner, 2006; Martiny *et al.*, 2006; Lindström and Langenheder, 2011). However, it is considerably more challenging to interpret these patterns in terms of the ecological and evolutionary processes that may generate them. A community assembly perspective that divides these processes into the effects of current environmental factors and the effects of historical processes is a common framework for evaluating the processes responsible for generating spatial biodiversity

patterns in macroorganisms (Ricklefs, 2007) and has been recently applied to microbes (Martiny *et al.*, 2006). Here “history” includes events from the very recent to the geological past that might have influenced present-day distributions, such as past environmental conditions or dispersal limitation. This framework draws many similarities to the metacommunity theory of community assembly, which has also been recently applied toward interpreting observed patterns in the biogeography of microbes (Lindström and Langenheder, 2011).

Following from traditional biogeography, one can consider a framework comparing the importance of the contemporary environment versus the legacies of historical processes for microbial biogeographic patterns. The contemporary environment includes abiotic variables (e.g., temperature, pH, and nutrient availability) as well as biotic factors such as the abundance and composition of other organisms. Historical events include anything from the effects of the past environment on the community, as well as evolutionary or ecological drift and speciation and extinction, which would cause differences in composition among localities. To observe evidence of historical processes, however, there must be dispersal limitation of some microbial taxa in the community, otherwise the effects would be long-since homogenized, and microbial composition would only depend on the current environment. This dispersal limitation allows for the effects of events in the recent or distance past to have a current signature on the microbial taxa present in a location.

Under this framework, one can consider four alternative hypotheses. The null hypothesis (Hypothesis 1 in Figure 4) is that microorganisms are not affected by the current environment or historical events. In this case, microbial taxa would be randomly distributed over space. Because there is no selection in the community by any contemporary environmental factor, there is no relationship between community similarity and environmental similarity (dotted line in Figure 4). Similarly, because there is no dispersal limitation of the microbial taxa, there are no lingering effects of historical events. Thus, community composition would not be correlated with geographic distance (solid line).

Hypothesis 2 is that microbial biogeography reflects the influence of the current environment, but no historical effects. This is the Baas-Becking hypothesis discussed above. None of the taxa is dispersal limited, thus historical events do not influence present-day assemblages. As a result, community similarity is correlated with environmental similarity, but once this relationship is accounted for, there is no correlation between community similarity and geographic distance. A key point here is that the effect of the current environment must be first statistically removed before testing for a remaining correlation with geographic distance, as environmental variables are usually spatially autocorrelated.

A third alternative (Hypothesis 3) is that all spatial variation in microbial composition is due to dispersal limitation and resulting historical effects. Finally, Hypothesis 4 proposes that, like macroorganisms, microorganisms (or at least some taxa within a community) are both dispersal limited and under current environmental selection. As a result, the distance–decay curve can be partitioned into a correlation

Figure 4 The relationship between community similarity and geographic distance (solid line), or environmental similarity (dotted line) for four hypotheses of microbial biogeography. As described in the text, the relationships depend on the degree of dispersal and the effectiveness of environmental selection.

with the environment as well as a remaining effect of geographic distance.

Evidence for the Importance of Contemporary Environmental Factors

To assess the importance of selection by the current environment on microbial composition (hypotheses 2 and 4; **Figure 4**), biogeography studies examine the correlation between community composition with measured environmental variables. In fact, almost every microbial biogeography study observes some such relationship between similarity in community composition and similarity in environmental characteristics of those samples. For example, numerous studies have linked spatial variation in microbial communities to variation in pH or salinity (e.g., *Fierer and Jackson, 2006*). Other studies have demonstrated that broadly defined habitat types, which are a proxy measure for a range of associated environmental variables, harbor significantly different microbial communities (e.g., *Nemergut et al., 2011*). Additionally, seasonal variation in microbial communities tends to be significantly correlated with variation in environmental variables (*Fuhrman et al., 2006; Gilbert et al., 2009*). Together these studies provide support for the importance of environmental variation in explaining why microbes are nonrandomly distributed in time and space.

Evidence for the Importance of Historical Factors

In contrast, variation in microbial community composition in space may arise because not all taxa can disperse to or

establish in all locations equally (hypotheses 2 and 4, **Figure 4**). Assessing the importance of historical factors in shaping biogeographic patterns is not straightforward, however. Because the movement and establishment of microbes is difficult to observe, the degree of dispersal limitation for microbes is often interpreted from the observed correlation between microbial community composition and geographic distance, after removing the influence of contemporary environmental factors. Since environmental variation is often spatially structured, as in a cline or gradient, controlling for this variation, either experimentally or statistically, is key to observing the effect of historical factors.

When microbial biogeography studies use this approach, some find a correlation between microbial composition and geographic distance after removing the effect of the contemporary environment (e.g., *Cho and Tiedje, 2000; Whitaker et al., 2003; Martiny et al., 2011*). Such studies provide evidence that historical factors, manifested by some dispersal limitation, can indeed be responsible for creating biogeographic patterns in microbes. Moreover, it suggests that not every microbial taxon is cosmopolitan; in other words, not every microbe is everywhere.

At the same time, many other studies find no evidence for dispersal limitation in microorganisms (e.g., *Finlay, 2002; Fierer and Jackson, 2006; Van der Gucht et al., 2007; Cermeño and Falkowski, 2009; Zinger et al., 2011*). Thus, a current question in the field is to uncover when and where dispersal limitation in microorganisms is more likely. In addition, if there is dispersal limitation, it remains to be investigated what historical processes are creating the signal (e.g., drift, speciation, extinction, or past environmental legacies).

Caveats to Interpreting Biogeographic Patterns

A balance between both contemporary environmental factors and historical processes likely shapes natural microbial communities. However, unraveling the importance of environmental selection, dispersal, and historical factors from observations of biogeographic patterns is not straightforward. First, these processes are likely to be highly intertwined over multiple scales of time and space (Rosenzweig, 1995; Ricklefs, 2007), and pinpointing the singular influence of any particular process within natural communities will be difficult. Second, multiple processes can result in identical patterns, yet many of the underlying processes cannot be directly measured or observed. Therefore, the observation of the existence of a particular biogeographic pattern does not prove the importance of any process.

Additionally, identifying underlying processes from biogeographic patterns is particularly difficult for microbes, as there is a limited understanding of microbial diversity. The physiological requirements and ecological interactions of the majority of microbial taxa in nature are unknown, so it is quite likely that many important selective factors of microbial habitats go unmeasured. For example, species interactions, such as predation, competition, facilitation, or mutualism, are generally under-considered in biogeographic studies of free-living microbes. Nonetheless, these interactions can alter taxonomic occurrences in space and may be strong forces in determining the habitable ranges of some microbes. For instance, Zinger *et al.* (2011) found that the composition of bacteria, archaea, and fungi in alpine soils were significantly correlated with plant species composition, with other abiotic environmental and spatial factors being less important. In general, if any unmeasured, yet selective, habitat features are spatially structured, they can produce a spurious correlation between microbial composition and geographic distance. This would lead to a potentially false conclusion that the biogeographic pattern is shaped by historical factors.

Dispersal is also particularly difficult to quantify for microscopic organisms, and thus geographic distance is used as a proxy indicator for the degree of dispersal between locations. However, this does not adequately represent the nature of the processes involved because successful dispersal is dependent on both the movement of a viable propagule in space and its successful establishment and colonization of a location. The lack of either movement or establishment, therefore, can produce a pattern consistent with dispersal limitation. The difference between these two, while seemingly subtle, could be the result of different ecological processes. For instance, lack of establishment may be caused by unfavorable local habitat conditions or biotic interactions (known as priority effects), whereas degree of movement may be a primarily stochastic process, especially for microbes, which are dispersed mostly by passive means. Therefore, the interpretation of microbial biogeographic patterns would be facilitated by future work on the importance of movement versus establishment. This insight could be attained by use of experimental manipulations, or by measuring the presence of microbial taxa in dispersal vectors such as air and rain.

Future Considerations

Evidence suggests that many microbes exhibit biogeographic patterns, and that these patterns are likely shaped by a combination of ecological and evolutionary processes, similar to animals and plants. However, while at least some microbes are dispersal limited, the importance of the contemporary environment is often more prominent than that of historical effects. Thus the future of microbial biogeography lies in identifying the conditions under which the relative importance of these underlying processes may vary. For example, response to environmental conditions and dispersal abilities may differ by taxonomic groups, taxonomic resolutions, habitat types, and spatial scales. If so, then the ability to detect biogeographic patterns and the importance of particular underlying processes may vary by scope, scale, and focus of the study. Here, some of the conditions under which biogeographic patterns may vary for microbes are highlighted, a consideration of which may facilitate detection of particular underlying biogeographic processes.

Taxonomic Focus and Resolution

Microbial taxa likely vary in traits that affect their dispersal and colonization abilities or their response to the environment, thereby influencing their distributions. Such traits include body/cell size, spore formation, and other dormancy life stages, or the ability to associate with other biological entities that could serve as dispersal vectors. Body size is thought to be negatively correlated with dispersal ability, whereby smaller organisms disperse farther than larger ones (Fenchel and Finlay, 2004). Additionally, spore formation and dormancy stages can increase the likelihood that a dispersing microbe will survive migration, allowing it to potentially travel greater distances until reaching a suitable habitat (Lennon and Jones, 2010). Microbial taxa also vary in traits that could affect the ability of migrants to colonize and establish in new locations through their response to the external environment. Some of these traits could include differential growth rates, “specialist” versus “generalist” physiologies, and susceptibility to pathogens or predators. Generalist taxa, for example, might be more resilient to environmental variation, and thus are able to colonize a larger range. Thus the relative importance of environmental variation and dispersal limitation may vary depending on the microbial taxa examined.

The ability to detect variation in microbial community composition, a necessity of the microbial biogeography study, is highly dependent on the level of taxonomic resolution used to define taxa. Taxonomic resolution is primarily constrained by the sensitivity of the identification method, and can also be arbitrarily defined in sequencing studies via sequence similarity cutoff values. Communities defined by low-resolution definitions or techniques may “lump” together taxa that vary in traits, obscuring differences between the relative importance of environmental selection and dispersal limitation among taxa. As for animals and plants, such broad-level taxonomic groups, akin to genus or family levels, are expected to have larger distributions than a particular species within a genus (Martiny *et al.*, 2006). Thus, biogeographic patterns may be

generally weaker (e.g., Horner-Devine *et al.*, 2004), and the underlying processes more intertwined, when microbial taxonomic definitions are broader.

Habitat Type

Habitat continuity could influence dispersal and therefore its relative importance in shaping biogeographic patterns. Highly connected habitats should be more linked via dispersal, thus harboring more similar communities (Lindström and Langenheder, 2011). Moreover, habitat types vary in degree of connectivity and the mechanisms of dispersal utilized by organisms in those habitats. Aquatic systems, for example, likely facilitate passive dispersal due to the fluidity of the medium. In contrast, movement of microbes may be more restricted within a more solid matrix such as soil. Therefore, microbial communities associated with solid substrates or “patchy” habitat types are expected to be more limited by dispersal than those in highly connected systems, such as the open ocean. Moreover, a biogeographic study across environmental gradients or across habitat types results in large amounts of environmental variation, and thus emphasizes the strength of environmental selection. In this situation, the influence of historical factors could be relatively weak, and possibly undetectable. Thus to target the potential effects of historical processes, habitat variability should be controlled for both via sampling design and statistical methods.

Spatial Scale

The ability to disperse from one location to another should decrease as the distance between those locations increases (Nekola and White, 1999). Accordingly, dispersal limitation should become more apparent as the spatial scale increases. This could result in a greater relative importance of historical factors at larger spatial scales. At the same time, clumping of animal and plant taxa due to restricted dispersal also happens on very short spatial scales. This small-scale clumping could very well be important in some microbial habitats such as biofilms and sediments (Martiny *et al.*, 2011). Thus, the spatial scale at which biogeographic patterns emerge for microbes may provide some insight into the degree of microbial dispersal that leads to certain biogeographic patterns.

Conclusions

Microorganisms exhibit patterns in their distributions across space at multiple scales, but given the immense diversity of microbes and their ecological roles, microbes are probably not uniformly shaped by the same ecological and evolutionary processes. The distributions of free-living microbes do appear to be influenced by both environment and history, with the relative importance of these depending on spatial scale, taxonomic resolution, habitat continuity, and life history traits. While at least some microbes appear to be dispersal limited, it is often secondary to the influence of the contemporary environment. Thus far, these conclusions are broadly similar to macroorganisms, although the relative strength of the underlying processes and particular environmental factors may vary.

The motivation for understanding microbial biogeography extends beyond drawing and interpreting a map of microbial diversity. Understanding microbial biogeographic patterns aids in investigating a range of microbial ecology questions – for example, how much and on what scales to sample microbial diversity, the nature and rate of microbial diversification or speciation, and the role of microbes in ecosystems. In fact, microbial composition drives a number of ecosystem processes, including decomposition, autotrophic and heterotrophic production, and nitrogen cycling. Therefore, even under similar environmental conditions, microbial communities in different regions might function differently. A better understanding of microbial biogeography is essential to predict the effects of microbial diversity on ecosystem functioning.

Glossary

Aerobe An organism that utilizes or requires the presence of oxygen for growth.

Anaerobe An organism able to grow in the absence of oxygen.

Autotroph An organism able to utilize carbon dioxide as its source of carbon.

Barotolerant and barophilic Able to tolerate high pressures and growing better under high pressure.

Bioluminescence Light production by living organisms.

Chemotroph Organisms that utilize chemicals as sources of energy.

Cryptoendolithic Living within the surface of rocks.

Elective culture The provision of appropriate physical and chemical conditions that elicit the growth of specific metabolic types of microbes.

Extremophile An organism that grows better at, or requires for growth, extremes of temperature, pressure, salinity, or other environmental factors.

Halophile An organism requiring high levels of salts for growth.

Heterotrophy An organism that obtains its carbon from organic carbon compounds.

Microbes Single-celled organisms, such as bacteria, archaea, protists, and unicellular fungi.

Phototroph An organism utilizing the energy of light, as in sunlight, for growth.

Psychrophile An organism that grows better at low temperature or requires low temperature for growth.

"The key to taking the measure of biodiversity lies in a downward adjustment of scale. The smaller the organism, the broader the frontier and the deeper the unmapped terrain" (Wilson, 1994).

Introduction

Rapidly accumulating evidence indicates that microbes most likely account for the vast majority of kinds of organisms on earth. Microbes carry out a stunningly diverse array of metabolic activities, several of which were instrumental in creating conditions for the evolution of other life forms. Through their colonization of diverse and extreme environments, their geochemical cycling of matter, and their biological interactions among themselves and with all other organisms, microbes define the limits of the biosphere and perform functions essential for ecosystem development and health. However, because microorganisms are predominantly unicellular life forms that generally are smaller than can be seen with the unaided eye, they historically have received disproportionately little scientific attention compared to that given to animals and plants. This lack of attention has begun to shift recently as awareness of the diversity of microbes and their biological importance has grown. Of the three presently recognized domains of life, two, the Bacteria and the Archaea, are entirely microbial, and the third, the Eucarya, through its vast array of protists and fungi, is primarily microbial. The essence and full scope of the diversity of microbes is revealed in the dramatic differences among these microorganisms in their phenotypic characteristics of cellular metabolism, physiology, and morphology, in their ecological distributions and activities,

and in their genomic structure, expression, and evolution. Appreciation for the true extent of microbial diversity is growing rapidly through the development and use of molecular phylogenetic approaches, which are enabling rigorous analysis of the origins and evolution of microbial life. In combination with classical methods of elective culture, isolation, and phenotypic analysis, the approaches of molecular phylogeny are stimulating the discovery of multitudes of new microorganisms, opening up their biology for study, and providing a clear understanding of the importance of microorganisms as the functional and evolutionary foundation of the biosphere.

The Scope of Microbial Diversity

We live on "a microbial planet" (Woese, 1999) in the "Age of Bacteria" (Gould, 1996). Microorganisms, the first cellular life forms, were active on earth for more than 3.0 billion years before the development of multicellular, macroscopic life forms. During that time and continuing into the present, through the invention of a spectacular array of different metabolic and physiological capabilities, microbes evolved to exploit the multitude of environments and microhabitats presented by the abiotic world. They thereby obtained the cellular building materials and energy necessary for growth and reproduction. In so doing, however, they progressively altered the geochemical conditions of the planet, leading to a continual development of new conditions and habitats, abiotic and biotic. Those new conditions and habitats presented both challenges to survival and opportunities to exploit,

leading to continuing evolution of distinct microbial types able to endure or take advantage of the biogeochemical changes taking place on earth. Once cellular life began, it is likely that no place on earth containing the molecules and energy conducive to life remained abiotic for long.

The evolutionary trend toward greater complexity, seen in the relatively recent appearance of multicellular life forms (e.g., plants and animals), however, did not cause microbes to be displaced. The appearance of plants and animals did not shunt the unicellular microbes to forgotten corners of the biosphere to hang on and eke out a marginal existence. Instead, multicellular organisms, which themselves can be viewed as highly evolved, complex assemblages of microorganisms, have provided unicellular microbes with a wide variety of new habitats to colonize and exploit. Consider the various microbes whose growth is favored by the different and changing habitats provided by the growth and senescence of roots, stems, leaves, flowers, and fruits during the life of plants. Consider the multitude of physicochemically distinct habitats of the human skin, of our mucous membranes, and the changing environments of our complex intestinal system. Along with these habitats, colonized often by assemblages of several different kinds of microbes, consider the species-specific developmental and metabolic symbioses certain bacteria have established with plants, such as nitrogen-fixing *Rhizobium* with legumes, and with animals, such as bioluminescent *Vibrio* with marine cephalopods and fishes (Figure 1). Instead of passing on the torch of preeminence in life to the developing multicellular organisms and then politely withdrawing from the life center stage, microbes were full participants and driving forces in that development, they have continued to diversify, and they remain fully dominant. Plants and animals provide a highly visible but thin multicellular skin over a biologically rich and complex microbial world. A sense of the biological dominance of microbes is given by estimates of the total number of living bacteria,

roughly 5×10^{30} cells, with a collective biomass, despite their small size, possibly equal to that of all other life forms (Whitman *et al.*, 1998). We live in the once-and-always age of microbes.

Microbes of one kind or another, especially bacteria, survive and grow almost everywhere on earth. Whether widely distributed, having been spread globally by winds, water currents, and animals, or occurring only in localized areas where they have adapted to grow under specific environmental conditions, microbes dramatically extend our perception of the limits of the biosphere. Previously, that perception was shaped to a large extent by our notion of the conditions under which plants and animals can live. As aerobic organisms, we require the high levels of oxygen present in air for survival. While many bacteria utilize oxygen as we do, most, however, grow best at lower oxygen levels, and anaerobic microbes of many different types require the strict absence of oxygen to survive, as found, for example, in sediment and gut tracts. Temperatures that from a human perspective are extreme—from just below the freezing point of water in some oceanic waters and sea ice, to several degrees above its boiling point in waters near hydrothermal vents and in hot springs—are not extreme at all to the bacteria that colonize these habitats. Indeed, water temperatures considered cold for humans (i.e., 15 °C) can be lethally hot to true cold-loving, psychrophilic bacteria. Barotolerant and barophilic bacteria, active at and requiring the extremely high pressures of the deep sea, exist at pressures that would crush the human body, while other microbes, the halophiles, found in salt lakes and solar evaporation ponds, require salt concentrations that would quickly pickle our tissues. Add to this the cryptoendolithic microbes living just below the surfaces of sandstone in the Antarctic, the acid-tolerant and acid-requiring bacteria of acid mine drainage and sulfur springs, and the alkalinity-requiring bacteria of desert soils and alkaline lakes that live at pH levels that would be caustic to our skin. This array of

Figure 1 Light-micrograph of a section of the light organ of the sepiolid squid *Euprymna scolopes*. The animal harbors a dense population of the luminous marine bacterium *Vibrio fischeri* extracellularly within a ventral tissue complex, the light organ, and uses the light produced by the bacteria in predator avoidance.

microbial attributes gives a sense of the physical and chemical extremes at which certain bacteria survive and grow (Madigan *et al.*, 1999). These organisms have no “protection” from the environment other than their inherent metabolism and physiology, which, instead of protecting them, exquisitely suit them to living in these extremes, on which they are dependent. Major research initiatives around the world seek to expand knowledge of “extremophile” biology identifying these “exotic” microorganisms and bringing into study the metabolic and physiological attributes that adapt them to life at the physical and chemical limits of the biosphere.

What about microbial diversity in less extreme environments, away from the limits of the biosphere? Many environments, such as garden soil, coastal seawater, and lake sediments, do not exhibit such dramatic extremes of temperature, acidity, pressure, or other factors. Microbial life in these environments is strikingly diverse. While many different types of microbes can be isolated and grown in laboratory culture from these environments, most so far cannot. A typical expectation is that much less than 1 percent to a few percent of the microbial types seen in an environmental sample will grow in culture (e.g., Amann *et al.*, 1995). That means the vast majority of microbes, even from commonly studied environments such as coastal seawater, have not been brought into study or identified. Thus, discoveries of new types of microbes are waiting to be made, and they are being made. Examples of the unexpected include the discovery of magnetotactic bacteria, which synthesize intracellular chains of magnetic granules that orient the cells to magnetic fields (e.g., Amann *et al.*, 1995) and the occurrence of new members of presumably anaerobic Archaea in oxygenated seawater at shallow depth (e.g., DeLong, 1998). These reports demonstrate that microbial life in more accessible and commonly encountered environments is still poorly understood and far more diverse than presently known or expected. Therefore, most habitats that are known to be rich in microbial life and that have been sampled, such as seawater, soil, and animal gut tracts, have not yet yielded for study anywhere near their full complement of microbes. And what about easily accessible habitats likely to be rich in microbial life that have not yet been examined at all or at best have been sampled only minimally? One type of habitat is the gut tracts of the several hundred thousand known insect species, only very few of which, such as the termite, have been examined microbiologically. Yet the gut tract of each species—because of the different foods the animal eats, the gut specific morphology and physiology for digesting that food, and the environmental conditions under which the animal lives—is likely to host its own very different kinds of microbes. Our “microbial planet” is largely unexplored.

The Biological Significance of Microbial Diversity

Microorganisms are “the foundation of the biosphere” (Staley *et al.*, 1997), providing its “essential, stable underpinnings” (Woese, 1999). Microorganisms have played and continue to play fundamental roles in the evolution of higher life forms on earth. They have done so and continue to do so through the essential ecological processes they carry out in obtaining

the materials and energy needed for growth and reproduction. A primary example of the evolutionary role microbes have played is oxygenic photosynthesis, invented by phototrophic bacteria more than 2 billion years ago and which releases oxygen as a by-product of energy generation. Over time, that release of oxygen led to a gradual change in the earth atmosphere from reducing to oxidizing. The oxidizing atmosphere, as it developed, allowed energetically more efficient aerobic organisms to evolve and provided a protective shield of ozone against ultraviolet radiation for terrestrial and aquatic organisms. Equally striking examples are the bacterial endosymbiotic origins of chloroplasts, light-harvesting organelles in plants, and of mitochondria, energy-generating organelles, major events in the evolution of plant and animal lineages in the Eucarya. Furthermore, the fixation of atmospheric nitrogen, reducing nitrogen gas to ammonium and converting it into organic nitrogen forms, is an entirely bacterial activity, carried out by various symbiotic and free-living microbes (Madigan *et al.*, 1999).

The ecological processes carried out by microorganisms are equally fundamental. For example, global biogeochemical cycles of major elements, carbon, nitrogen, sulfur, and iron, essential components of all living cells, operate through microbial activity. Specifically, degradation of complex carbohydrates such as chitin, forming the exoskeleton of arthropods, and cellulose, hemicellulose, and lignin, structural polymers in plants, is essential. Without microbial conversion, these polymers would accumulate, removing huge amounts of carbon from the biosphere and blocking a multitude of biological processes that allow micro- and macroorganisms to live. In the absence of these microbial degradative processes, life on earth would soon falter. Besides the microbial degradation of complex organic compounds, consider the range of metabolic diversity in microbes, from oxygenic and anoxygenic photosynthesis, sulfate reduction, methanogenesis, denitrification, iron oxidation, nitrite oxidation and nitrate reduction, hydrogen and methane oxidation, and so on, all ways by which microbes obtain the energy necessary for growth and reproduction. These considerations form in part the basis for a commonly held view that bacteria and other microbes, in carrying out these processes, serve humans and other higher organisms as environmental recyclers and bioremediators. That view, while essentially correct, overlooks an essential point—these activities and processes are the fundamental biology of this planet. Microbes are the biosphere; their activities create and provide the foundation for all other life.

To gain a perspective on the significance of microbial diversity, imagine a biological survey crew tasked with discovering and documenting life forms on a newly encountered planet. Consider that upon landing, the crew found, remarkably, no macroscopic life. However, suppose that an initial sampling of a cubic centimeter of the planet surface revealed the presence of millions of discrete microscopic cellular entities. Imagine that with much additional analysis these entities were found by the crew to represent thousands of different kinds of organisms, distinguishable by their morphology or their dramatically different ways of obtaining the energy and nutrients necessary for metabolism and reproduction. Would the survey crew be surprised? What if upon

analysis of the genetic material from the different types present, these microbial life forms were confirmed to be different and were found in many cases to be dramatically more distinct from each other evolutionarily than are seaweeds and humans, would the crew be impressed? What if the crew continued sampling, spreading out and choosing other locations of the planet surface, and found similar “species richness” wherever they looked, but often with little or no overlap in the types of entities present from one environment to the next. Would that start the crew thinking about, to paraphrase E. O. Wilson (1994), “a strange and vastly complex living world virtually without end”? It would, of course. However, there is no need to invoke new planets. This imaginary scenario describes the reality of microbial diversity on earth. The only difference is the microbially driven evolution of macroscopic life forms on earth, giving rise to the plants, animals, and macroscopic fungi.

A New Era in Biological Sciences

Despite the complexity and richness of microbial life and the essential evolutionary and ecological roles played by microbes, awareness of microorganisms remains limited. The diversity and scientific importance of microbes have been largely passed over in human society, in science, in biology, and even in discussions of biodiversity (Hawksworth, 1991), overshadowed by attention to macroscopic forms. The prevailing and erroneous view for many biologists is that bacteria are “primitive, simple and relatively uniform” (Pace, 1996). This view developed naturally from early technical and scientific limitations for discovering and studying bacteria and other microbes in the 18th and 19th centuries, such as the need for high-resolution microscopy and the need to understand cellular structure, biochemistry, polypeptides, and nucleic acids. Such limitations did not hinder as starkly the beginnings of microbiology. Later, as limitations to the study of microbial life were overcome in the first three-quarters of the 20th century, the bias against microbes as scientifically important biological systems was nonetheless maintained and reinforced through the lack of a comprehensive phylogeny of microbes. This situation was especially true for bacteria, which generally lack distinctive morphological characters and for which sexual reproduction like that of plants and animals is absent. That bias remains largely extant today. For example, most college and university departments of biology and biological sciences are staffed predominantly with animal and plant biologists, with relatively few if any microbial biologists. Yet “the incongruity (between the scientific perception of microbiology and the preeminence of microorganisms in the real world) is astounding; it is worrisome; it cannot be scientifically justified or tolerated” (Woese, 1999). Fortunately, the bias and incongruity are beginning to be eliminated.

The “Delft School” of General Microbiology

The confluence of two distinct but complementary approaches in biological science, one classical and one more recent, is leading to a shift in awareness about microbial diversity and

its scientific importance. The classical approach is that of elective culture, also referred to as enrichment culture, by which new microbial types are brought into culture and isolated for phenotypic analysis. The elective culture approach, through the careful design of growth media and conditions, seeks to provide an appropriate physical and chemical environment that, when inoculated with an environmental sample (mud, for example), will elicit the growth of specific metabolic types of bacteria postulated to be active or present in the sample. For success, the approach requires a thorough knowledge of biochemistry, good observational skills, and sensitivity to potential novelty in microbial metabolism and physiology. A recent example of this approach, demonstrating its central importance and value in microbial research, is the isolation of acetogenic spirochaete bacteria from the hindguts of termites (Leadbetter *et al.*, 1999). Spirochetes are major members of the diverse microbial consortium resident in the termite hindgut (Figure 2), and they have been thought to play key roles in the insect nutrition, which is based on

Figure 2 Phase contrast micrograph of the contents (diluted) of the hindgut of the termite *Reticulitermes flavipes* (Kollar). The microbial assemblage of this common eastern subterranean termite includes several types of microbes, including a variety of different kinds of spirochetes, both free and attached to cellulolytic protists. H_2 and CO_2 , formed during microbial cellulose digestion, are converted by certain of the spirochetes to acetate (Leadbetter *et al.*, 1999) a major source of nutrition for the animal. The different spirochaetal cells range in length from approximately 5 μm to over 30 μm .

microbial degradation of cellulose and conversion to acetate, a major carbon and energy source for the insect. However, no spirochetes from the termite gut previously had been isolated in pure culture. That inability limited knowledge of the contribution these morphologically distinct and numerically significant bacteria make to host animal nutrition. Leadbetter and coworkers, however, successfully established culture conditions that favored the growth of spirochetes over other bacteria and that simultaneously encouraged the growth of bacteria able to form acetate, from H_2 and CO_2 , breakdown products of cellulose degradation. In this way, acetogenic spirochetes from the termite hindgut were brought into pure culture for the first time. H_2/CO_2 acetogenesis, a type of metabolism previously unknown among spirochetes, reveals an important way, formation of acetate, in which these bacteria contribute to termite nutrition. The ability to design culture conditions that elicit the growth of specific bacterial types known or suspected to be present in an environment is central to development of our understanding of microbial diversity and microbial ecology. Once a novel microbial type has been brought into culture, that organism's special or unique cellular metabolism, physiology, and genetics can then be studied in detail.

This now classical elective culture approach developed through the insights of Sergei Winogradsky, a Russian soil microbiologist, and Martinus Beijerinck and later Albert Kluyver, Beijerinck's successor, in Delft, Netherlands. Their work was instrumental in forming the foundations of general microbiology and microbial ecology. When Cornelis van Niel, a student of Kluyver, moved in 1928 from Delft to the Hopkins Marine Laboratory in Pacific Grove, California, he brought with him the "Delft School" tradition in microbiology, which he continued and further developed through his research and through a course he taught in general microbiology and comparative biochemistry (van Niel, 1949). Through his course van Niel trained a generation of microbiologists. Those individuals have gone on to use the Delft School, van Niel approach, in their research, and they in turn have taught other generations of microbiologists, further disseminating the Delft School tradition. Most notably today, the elective culture and isolation approach to the study of metabolically and ecologically diverse bacteria is fostered in young microbiologists and other scientists through the Microbial Diversity summer course of the Marine Biological Laboratory in Woods Hole.

The "Woesean Reformation" of Microbiology

Despite the progress arising from the Delft School tradition in exploring and defining the diversity of bacteria and their metabolic capabilities, a major problem limited the development of general microbiology in the first three-quarters of this century: the lack of a unifying phylogeny of microorganisms. Various efforts at classifying bacteria and systematizing relationships among them, based on phenotypic characters of morphology and biochemical growth attributes, were attempted and abandoned. The frequent lack of characters, the instability or the shared nature of many characters, and the awareness that phenotypic characterization was not grounded

necessarily at the genetic level left these efforts with major flaws. The inability to place microbes, especially bacteria, in an evolutionary context caused general microbiology and microbial diversity largely to languish as mainstream sciences at a time when other areas of biology and microbiology (e.g., clinical microbiology and biotechnology) were developing rapidly (Woese, 1999). What was needed was a unifying phylogenetic framework, founded at the genome level, which would allow the true evolutionary relationships among microbes to be analyzed critically and defined.

The use of informational macromolecules, begun more than 30 years ago, is now fulfilling that need for a unifying phylogeny of microbes (Woese, 1987; 1999) and is reforming our view of the evolution and diversity of microbial life. Analysis primarily of ribosomal RNA (rRNA) sequences, especially for the small subunit 16S and 16S-like rRNAs, has created "the first valid microbial phylogenetic systematics" (Jannasch, 1997). The functionally constant 16S and 16S-like molecules, common to all organisms, contain evolutionarily highly conserved regions, suitable for comparing less closely related organisms, and more variable regions, suitable for assessing evolutionary relationships in more closely related organisms. The universality of ribosomal RNA extends the value of this sequence comparison approach to all life forms, but importantly for bacteria it has established a unified phylogenetically based system with which to begin defining bacterial evolutionary relationships, a "first step in microbiology reformation" (Woese, 1999). Along with 16S rRNA, other molecules, such as elongation factor Tu, 23S rRNA, and F_1F_0 ATPase, also provide substantial phylogenetic information and can serve as alternative markers for inferring relationships (Ludwig and Schleifer, 1999). A variety of opportunities exist at various institutions for learning the principles and application of molecular phylogenetic analysis in microbes and higher organisms. Notable among them is the Marine Biological Laboratory course in Molecular Evolution, an intensive 3-week course dedicated to these topics.

A second step in the Woesean reformation of microbiology is the application of rRNA-based molecular phylogeny to microbial ecology (e.g., Hugenholtz *et al.*, 1998; Pace, 1996). Sequence analysis of 16S rRNAs, for example, extracted from natural environments provides direct access to the diversity of bacteria in that environment, bypassing the need for culturing microbes and giving a rapid and potentially comprehensive assessment of microbial community composition. rRNA-based approaches have opened up for study many microbial activities and associations. The result is a rapidly expanding awareness of the diversity and ecology of microbes, both culturable and not-yet-cultured (Amann *et al.*, 1995; Hugenholtz *et al.*, 1998; Pace, 1996, 1999).

The strengths of the elective culture and molecular phylogeny approaches make them naturally complementary. The cultivation of a new microbe leads to acquisition of the organism 16S or 16S-like rRNA sequence in the context of data on its metabolism, physiology and habitat. That sequence provides a defined point of phylogenetic reference and a highly specific tool with which to examine the organism distribution in the environment. Equally exciting is the opportunity to examine and explore the environment for the full, natural microbial diversity present, without concerns about

the bias inherent in and finesse required for culturing. Those explorations identify and define more deeply within a unified phylogenetic framework the diversity of microbes present while also offering potential insights into their metabolism and physiology. That information, in turn, can motivate more refined or novel attempts at cultivation of the sequence-identified microbes. Each approach nurtures and magnifies the strengths of the other. For microbiology in the next century truly to “emerge as the primary biological discipline” (Woese, 1999) the continuing confluence of these approaches must be encouraged.

Major Groups of Microbes

Through analysis primarily of 16S and 16S-like rRNA genes, microorganisms can now be placed in a potentially

comprehensive phylogenetic framework, one that includes all living organisms and therefore is universal. Examination of the 16S and 16S-like rRNA-based universal phylogenetic tree (Figure 3) shows the three currently proposed domains of life, Bacteria, Archaea, and Eucarya. Future analyses, using expanding sequence data sets and markers of phylogenetic relationships other than 16S and 16S-like rRNA (Ludwig and Schleifer, 1999) will serve to test and refine the validity of this evolutionary grouping. Regardless, the current universal tree reveals in a simple, compelling way the dominance of microbial life forms. The true diversity of life is microbial.

Domain Bacteria

The unit of biological diversity is the species. The classical concept of a biological species, a reproductively isolated interbreeding or potentially interbreeding population of

Figure 3 The universal tree of life. The three domains of life, Bacteria, Archaea, and Eucarya, represented by small-subunit rRNA sequences of various organisms within each domain, are shown. The domain Bacteria (Eubacteria) and the domain Archaea (previously the archaeobacteria) are entirely microbial, and the domain Eucarya is predominantly microbial.

individuals, however, does not work for bacteria and other microbes that do not interbreed, that have undefined or cosmopolitan distributions, and that generally lack distinguishing morphological characters. So, in discussing bacteria, members of the domains Bacteria and Archaea, how is a species defined? The phylogenetic species concept, a group of individuals for which phylogenetic analysis has demonstrated a shared genealogical relationship (Alexopoulos *et al.*, 1996), seems more workable for bacteria and other asexually reproducing microbes. The question then becomes the extent of genealogical relationship between two individuals necessary to designate them as members of the same species. Operationally for bacteria, if the genomic DNA of two strains is 70% or more similar, as determined by DNA-DNA hybridization analysis, they are considered the same species. With respect to rRNA, 16S rRNA sequence, similarity values below 97% are a strong indication that the two bacteria are different species (Amann *et al.*, 1995; Madigan *et al.*, 1999). The combination of these two approaches, both based at the genomic level, is powerful. When further combined with the identification of distinguishing phenotypic characters, such as cell morphology, motility, and flagellation, response to oxygen, requirement for organic growth substrates, growth temperature range, special metabolic attributes, characteristics of the habitat, and so on, a character-rich, biologically meaningful description of a bacterial species can be obtained.

Conservative estimates place the total number of species of bacteria at 50,000 to 3,000,000 (e.g., Staley *et al.*, 1997). As of 1999, approximately 5000 bacterial species had been described (Pace, 1999), a very small portion of the estimated total number, though many of these descriptions do not yet include rRNA sequence information. Most easily accessible environments, even those commonly sampled for microbial life, are likely to contain a multitude of as-yet-uncultured bacteria. Another important consideration in estimates of the number of bacterial species is the extent to which microhabitats, habitats relevant from the microbe viewpoint, have been sampled. A reasonable assumption is that most biotic and many abiotic surfaces are colonized by bacteria. Each surface presents a different microhabitat and therefore is likely to be colonized by a different individual bacterial type or assemblages of types, with the "many different microenvironments creating an almost infinite variety of selective conditions" (Palleroni, 1994), that is, conditions selecting for the specific metabolic and physiological types. An estimated total number of plant and animal species is approximately 9 million, with insects making up the majority of those species (Staley *et al.*, 1997). Presumably, the external surfaces of these organisms, and also the mouths, gut tracts, and internal tissues of the animals, provide myriad types of microhabitats for bacterial colonization by assemblages of different microbes (Amann *et al.*, 1995) and in many cases by specific bacterial symbionts, as in the various nutritional endosymbioses between bacteria and insects. Consequently, these estimates of bacterial species must be too low. When the approximately 2 million species of fungi and protists, many of which undoubtedly also have largely different assemblages of microbes as well as specific bacterial symbionts, also are factored in, then the total number of bacterial species easily could exceed tens of millions. Future generations of microbiologists will

likely find even this estimate to be conservative. Regardless, however, of what the actual total number of bacterial species turns out to be, bacteria are stunningly diverse.

Previously, all bacteria were grouped together taxonomically as prokaryotes. That grouping was based primarily on the common lack of a membrane-bounded nucleus in bacteria. Prokaryotic organisms, however, are now separated phylogenetically into two domains, the Bacteria (or Eubacteria) and the Archaea (formerly the archaebacteria). The Archaea exhibit many similarities to the Eucarya, demonstrating that the prokaryotic body plan is not a phylogenetically definitive character. The bacteria exhibit a wide variety of ways of obtaining for growth the necessary carbon, as in the various kinds of heterotrophic and autotrophic microbes, and energy, as in phototrophic and chemotrophic microbes.

The domain Bacteria presently contains well over two dozen divisions, or kingdoms, of organisms (Figure 4). Madigan *et al.* (1999) suggest, however, that the true number of kingdoms in the Bacteria may be 50 or more. As the number of these groups indicates, physiological diversity within the Bacteria is profound. The diversity is especially striking in two of the kingdoms, the Proteobacteria and the Gram-positive bacteria (Madigan *et al.*, 1999), members of which exhibit a wide range of different metabolisms, physiologies, morphologies, and habitats. Examples among the Proteobacteria include the human enteric bacterium *Escherichia coli*, pathogenic pseudomonads, light-producing marine photobacteria, the fever-causing rickettsias, gliding bacteria and fruiting-body formers, stalked and budding bacteria, nitrogen-fixers, sulfate reducers, and so on. Within the Gram-positive kingdom are staphylococcal parasites of humans, the milk-sugar fermenting lactobacilli, and spore-forming soil bacteria, among many others. This diversity, however, probably reflects more the relative ease of cultivation and long-term scientific attention members of these two kingdoms have received than the true biological richness of the groups. One can anticipate that much more diversity in other kingdoms of the Bacteria will be revealed with time as bacteria are studied more intensively. Furthermore, as the fusion between elective culture and molecular phylogeny develops, many other types of bacteria, some entirely unexpected, will be discovered and will be found to warrant kingdom status. A recent text (Madigan *et al.*, 1999) highlights the different groups of bacteria, providing information on individual types within a phylogenetic context.

Domain Archaea

The domain Archaea includes the majority of presently known "extremophiles," organisms that live at physical or chemical extremes. Archaea increasingly are being discovered, however, in less extreme types of environments, including the marine plankton, lakes, and sediments (e.g., DeLong, 1998; Vetriani *et al.*, 1999). Diversity within the Archaea is presently less well understood than in the Bacteria and Eucarya because the Archaea often require particular care to culture. Knowledge of how to culture the Archaea has expanded in recent years, and additional habitats supporting their growth are being actively studied, so the disparity in the numbers of different kinds of

Figure 4 Diversity and phylogenetic relationships among members of the domain Bacteria. The division level grouping are of two types: currently recognized divisions, represented by cultivated bacteria (black), and provisional divisions, represented to date by environmental sequences (outline). The scale bar represents 0.1 changes per nucleotide.

Archaea compared Bacteria should progressively diminish. The Archaea consists at this time of three kingdoms, the Euryarchaeota, the Crenarchaeota, and a provisional kingdom, the Korarchaeota (Figure 5).

Two major types of bacteria, the methanogens and the extreme halophiles, are included within the Euryarchaeota. Methanogens are bacteria that produce methane as an end-product of energy conversion reactions; they occur in a variety of strictly anaerobic habitats, such as sediments, sewage sludge digestors, the rumen of cattle, and the termite hindgut. CO_2 and similar compounds, methanol and other methyl-containing compounds, and acetate are used by different members of this group as substrates for methanogenesis, often with H_2 as an electron donor. Methane, primarily from methanogenic bacteria, is an important greenhouse gas, accounting for possibly as much as a few percent of total primary production. Some methanogens, such as *Methanococcus jannaschii*, are hyperthermophiles. The extreme halophiles, represented by *Halobacterium salinarum*, are bacteria that require for survival and growth the exceptionally high salt concentrations found in salt lakes and solar evaporation

ponds. Other groups of Euryarchaeota include a lineage of extremely acidophilic bacteria containing *Thermoplasma* and *Picrophilus*, and two lineages of hyperthermophiles, represented by *Pyrococcus* and *Archaeoglobus* (Figure 4).

The Crenarchaeota contains a large and physiologically diverse group of hyperthermophilic, sulfur-metabolizing bacteria from terrestrial and marine hot springs and hydrothermal vents. Recently, several Crenarchaeota (and Euryarchaeota) have been identified at the 16 S rRNA level as members of the plankton in cold oceanic surface and deep waters, coastal sediments, lakes, and in association with animals, indicating that the Archaea are more cosmopolitan in their distribution than believed earlier (e.g., DeLong, 1998; Vetriani *et al.*, 1999).

A third kingdom of Archaea, the Korarchaeota, was established provisionally based on rRNA sequences obtained from samples of the Obsidian Pool hot spring in Yellowstone National Park and distinct from those of other Archaea (Pace, 1996). Attempts to bring these hyperthermophiles into pure culture are underway. The discovery of this third Archaeal kingdom and the recent discoveries of Archaea in cold, oxygenated habitats clearly indicate that the true diversity of

Figure 5 Diversity and phylogenetic relationships among members of the domain Archaea. This maximum likelihood tree, based on small-subunit rRNA, shows representatives of the Crenarchaeota (some extreme thermophiles and some marine environmental phylotypes) and of the Euryarchaeota (some extreme thermophiles, methanogens, halophiles, and marine environmental phylotypes). The environmental phylotypes are indicated with acronyms and numbers, with their environmental origins designated. *T. maritima* and *A. pyrophilus* form the bacterial out-group. The scale represents the expected number of changes per sequence position. See Vetriani *et al.*, 1999 for details and references. Prepared and provided by C. Vetriani, Rutgers University.

Archaea is likely to far exceed that based on presently identified species and sequences obtained from environmental samples. Implicit in this newly evolving view of Archaeal phylogenetic diversity are substantially broader metabolic capabilities and wider ecological roles for this group of bacteria (DeLong, 1998; Vetriani *et al.*, 1999).

Domain Eucarya

Microbial groups in the Eucarya are the Protista and the Fungi, organisms that, in contrast to the Bacteria and the Archaea, have a membrane-bounded nucleus. Endosymbiotic events are likely to have been major driving forces in the evolution of eukaryotes. Bacteria are thought to have diverged early from a universal prokaryotic ancestor, followed by the Archaea, both of which retained the prokaryotic body plan. Fusion of an archaean and a bacterium may have led to the nuclear line, which through symbiotic acquisition of phototrophic and nonphototrophic bacteria resulted in chloroplast- and mitochondria-bearing eukaryotic cells. Loss of one or both of these organelles, or failure to acquire them initially, along with secondary symbiotic events, can be seen to account for

much of the diversity of modern eukaryotes (Madigan *et al.*, 1999).

Previous groupings placed eukaryotes into four kingdoms: animals, plants, fungi, and protists, with a fifth kingdom, Monera, to contain all the bacteria. Current understanding of phylogeny indicates that this five-kingdom system greatly underemphasized the diversity of bacteria while overemphasizing animals and plants, as described earlier. The five-kingdom system also underrepresented the diversity within the protists. The current, developing view, based on a rapidly increasing database of 16 S-like rRNA sequence information, is that the Eucarya consists predominantly of unicellular microorganisms and that many phylogenetically deep, kingdom-level divisions exist within the protists (Sogin *et al.*, 1996). Diversity within the protists dominates that of the other eukaryotic lineages (Figure 6).

Protista

The Protista is a large complex grouping of mostly unicellular eukaryotic organisms. They are morphologically diverse and can be found in most terrestrial, aquatic, and marine habitats as free-living forms and as parasites of other protists, of fungi, and of plants and animals. With their nutritional modes

Figure 6 Diversity phylogenetic relationships among members of the domain Eucarya. This evolutionary tree reveals the dominance of the protists over the fungi, animals, and plants.

restricted primarily to osmo- and phago-heterotrophy and phototrophy, protists are metabolically much less diverse than Bacteria and Archaea. Along with various independent amoeboid groups, major groupings include the Alveolates, composed of ciliates (e.g., *Paramecium*), dinoflagellates (e.g., *Alexandrium*), and apicomplexans (e.g., *Plasmodium*), and the Stramenopiles, composed of the brown and golden-brown algae, diatoms, chrysophytes, oomycetes, and distinct groups of slime molds, among other groups. Cryptophytes, Rhodophytes, and Haptophytes are other major groupings of protists. Along with these groups are the diplomonads, trichomonads, microsporidia, amoeba-flagellates, and euglenoids (Figure 6).

Fungi

The fungi, *sensu strictu*, are commonly filamentous, multicellular heterotrophic organisms. Though previously thought to be similar to plants but lacking chlorophyll, fungi phylogenetically are not closely related to plants. Instead, fungi are seen now to have diverged from the animal lineage (Alexopoulos *et al.*, 1996). Many fungi are saprobic, feeding osmotrophically on dead organic matter, and many are also parasites or symbionts of animals. As such, they share the limited range of metabolic capability of animals. Approximately 69,000 species of fungi have been identified, and more than 1,500,000 species are estimated to exist (Hawksworth, 1991).

Figure 7 Diversity of fungi and the timing of their divergences. See Berbee and Taylor (1999) for details. Species names are abbreviated with the first five letters of the genus followed by the first three letters of the specific epithet for these fungi (e.g., *Dermocystidium salmonis* = Dermosal).

Four major groups (phyla) of true fungi have been defined (Alexopoulos *et al.*, 1996) (Figure 7). The Chytridiomycota contains a single class, Chytridiomycetes, which uniquely among fungi produces motile cells during its life cycle. The motility organelle, a typical eukaryotic flagellum, probably was retained from ancestral protists (Berbee and Taylor, 1999). Chytrids play important ecological roles in decomposing organic materials. The Zygomycota contains two classes, the Zygomycetes, which form thick-walled resting zygospores, and the Trichomycetes, obligate symbionts of arthropods. The Ascomycota, which form ascospore-carrying asci, contains most of the lichen-forming fungi. The Basidiomycota, which produces sexual basidiospores on specialized basidia, contains many of the commonly recognized fungi, such as mushrooms, puffballs, and bracket fungi. Plant pathogens in this phylum include the rust and smut fungi. Other fungi-like microbes commonly studied by mycologists now are grouped with the protists. These include the Stramenopile groups of oomycetes, hyphochytrids, and labyrinthulids, the plasmodiophorids, and the dictyostelid, plasmodial, and acrasid slime molds. The phylogenetic diversity and evolution of the fungi is an area of active research (e.g., Berbee and Taylor, 1999).

Concluding Comments

Understanding the extent and significance of microbial diversity "is the primary goal, the necessary objective, of biology in the next century" (Woese, 1999). Where progress toward that goal will take biology, however, is difficult to even guess, since the unexplored, unrecognized diversity of microbes is immense. However, the fusion of elective culture and molecular phylogeny is creating a revolution in our understanding of that diversity and of the ecological and evolutionary significance of microbes, especially bacteria. Molecular phylogeny also is overturning the previously limited view of protist diversity and is enhancing awareness of fungal phylogeny and diversity. Add to this microbial revolution, just underway in the beginning years of the 21st century, the developing influences of genomic sequencing, differential display and proteomics, and one sees a turbulent, radical, and exciting restructuring of biology underway, one that is being spearheaded by new awareness of the extent and significance of microbial diversity. Important beyond measure in the success of that restructuring will be attracting talented students to professions in microbial research. While biotechnological aspects of microbiology will continue to appeal to capable young researchers, many of the best students will be attracted not by the usefulness of microbes but by their inherent biological beauty and by the potential their study offers for insights into the evolution of life on earth.

Glossary

Fragment recruitment A computational technique in which reads from a metagenomic data set are mapped to a reference genome. This information allows for assessing the abundance and representation of an organism (given by its genomic sequence) in a microbial community (represented by the metagenomic data).

GOS The Global Ocean Sampling program launched by the J. Craig Venter Institute to study microbial diversity in the world's oceans using metagenomics.

Metagenomic assembly The process of inferring genomic sequences of taxa represented in a metagenomic data set. Reads that belong to the same genomic region are identified using read overlap information, and joined to produce longer contiguous sequences called contigs. When read mate-pair information is available, contigs can be further ordered and oriented to produce

scaffolds. An assembly is a collection of contigs and/or scaffolds.

Metagenomics Literally “beyond genomics,” this refers to the process of sampling the entire genetic complement of an environment via DNA isolation, sequencing, annotation, and informatic analysis.

MMGSP The Gordon and Betty Moore Foundation funded Marine Microbial Genome Sequencing project (MMGSP) was an international collaborative initiative whose goal was to sequence genomes of ecologically relevant microbes from the marine environment.

Picoplankton The fraction of aquatic biomass in the size fraction that passes through 3.0 and 0.8 μm filters, and is retained on a 0.1 μm filter.

Taxon A term describing a collection of organisms that are sufficiently closely related to be considered to be in the same taxonomic group (species, genus, etc.).

A Historical Perspective: The Need for Genomics and Metagenomics

From the early years of marine microbiology to the late 1970s, the microbial communities of the ocean were easily explained: the dominant groups were familiar to most microbiologists, and included heterotrophs such as *Vibrio*, *Pseudomonas*, *Alteromonas*, and *Photobacterium*, to name a few, as well as other geochemically active aerobes (e.g., familiar species of ammonia and nitrite oxidizers such as *Nitrobacter*; *Nitrosobacter*; sulfur oxidizers, methane oxidizers such as *Methanobacter*), and an impressive array of anaerobic taxa including methanogens and sulfate reducers (Kriss, 1963; Sieburth, 1979; ZoBell, 1946). Much of marine microbiology thus focused on the mechanism(s) and roles of these “key species” in processes such as bioluminescence, symbiosis, fish disease, elemental cycling of carbon, nitrogen, and sulfur, and the production or consumption of important nutrients in the ocean (Sieburth, 1979). At the level of primary productivity, the importance and abundance of the cyanobacterial genera (*Synechococcus* and *Prochlorococcus*) was not yet appreciated, and the view of oceanic carbon cycling was dominated by microalgae, and a few large filamentous cyanobacteria such as *Trichodesmium* (Pace, 1997; Sieburth, 1979).

In the ensuing decades, three key events occurred that forever changed the intellectual landscape of marine microbial diversity and ecology. The first was the “great plate count anomaly” (Staley and Konopka, 1985) and the accompanying realization that most of the microbes seen in the microscope did not form colonies on standard growth media (see Sieburth (1979) and references therein), thus leading to the

concept of the uncultivated or “unseen” majority (Whitman *et al.*, 1998). It became clear at this juncture that the “dominant species” represented neither marine microbial diversity nor marine microbial ecology in the broader sense. At this point, it seemed possible that the nongrowing microbes were simply uncultivable members of the “dominant taxa,” but since taxa were identifiable only by growth-related criteria, this could not be established.

Second, through the work of Carl Woese and his colleagues (Olsen *et al.*, 1986; Pace *et al.*, 1986; Pace, 1997; Pace *et al.*, 1986; Woese *et al.*, 1990), it became clear that the 16S rRNA gene sequences could be used to identify major groups of microbes, including many that remained uncultivated. Furthermore, through comparative sequence analysis, it became clear that the entire microbial world could be related via sequence similarity, using 16S rRNA gene sequences (Pace, 1997; Pace *et al.*, 1986; Woese *et al.*, 1990). Thus major clades of microbes were seen that were represented only by 16S rRNA gene sequences: i.e., they had no cultivated members. Examples of such organisms were SAR11 (now in cultivation as *Pelagibacter ubique* (Giovannoni *et al.*, 1990)) and SAR 86 (an abundant lineage that has still resisted all attempts at cultivation (Giovannoni *et al.*, 1990)). Molecular analyses of seawater soon revealed the presence of large numbers of some of these clades in seawater, particularly SAR11, and two groups of cyanobacteria – *Synechococcus* and *Prochlorococcus* (Rocap *et al.*, 2002; Worden *et al.*, 2000). With regard to microbial diversity, the notion that the “unseen majority” were simply nongrowing members of more familiar clades could now be dispensed with.

Third, through the work spearheaded by Waterbury (i.e., the cultivation of phototrophic microbes in the groups

Synechococcus and *Prochlorococcus*) (Rocap *et al.*, 2002; Waterbury *et al.*, 1979; Waterbury and Willey, 1988) and Giovannoni (i.e., the cultivation of SAR11 and several other *P. ubique* strains (Rappe *et al.*, 2002; Stingl *et al.*, 2007)), it became possible to do comparative physiology and to integrate the physiology with genomics of these newly cultivated groups.

With the advent of metagenomics (Handelsman, 2004), it became possible to study marine microbial communities using cultivation independent approaches. In a typical metagenomic study of an environment, nucleic acids are extracted from the collected sample and directly sequenced using a random shotgun approach, thus eliminating the need for *in vitro* culture.

Discovery Science: The Global Ocean Sampling (GOS) Program

The GOS Idea

The GOS program was launched by the J. Craig Venter Institute (JCVI) to study microbial diversity in the world's oceans using metagenomics. The program started with a study of samples collected from the Sargasso Sea (Venter *et al.*, 2004), and was followed by sampling of surface seawater from sites around the globe (Figure 1). At the very least, a picture of the taxonomic composition of microbes, both known and unknown, could be expected from this study: i.e., a metagenomic glimpse of surface ocean biodiversity could be expected. More optimistically one might hope for insights into the general

principles that guide adaptation and evolution of marine surface picoplankton. Seawater samples were collected (Rusch *et al.*, 2007) by pumping water through a 20- μm Nitex® pre-filter, and then size fractionating the biological material by serial filtration through 3.0, 0.8, and 0.1 μm membrane filters to obtain three size fractions; the final filtrate was also harvested to analyze for marine viruses. The collected filters were frozen, stored on dry ice, and shipped to the JCVI for sequencing as soon as possible. To this point in time the analysis of these samples has focused primarily on the microbes that pass through the 0.8 μm filter, and are retained on the 0.1 μm filter – commonly referred to as the picoplanktonic size fraction, or the picoplankton. Thus, any coccoid organisms smaller than 0.8 μm in diameter, and any rod-shaped organism with a diameter of 0.8 μm or less would have a good chance of passing through the filter. Accordingly, larger organisms, aggregated cells, and particle associated cells should all be retained on the larger filter(s).

The Sargasso Sea: A “Low Diversity” Site

The GOS began with a series of samples from the Sargasso Sea, chosen specifically because of its reported low biomass properties, and the expectation that it would also display low biodiversity. This expedition was regarded as a “test run” to develop and trouble-shoot the methods of sample collection, sequencing and analysis pipelines, and annotation and assembly methods. How would this approach compare to estimates of biodiversity obtained by other methods? (Giovannoni *et al.*, 1990) The Sargasso Sea waters have on the order of 10^5 cells per ml of seawater, about a factor of 10 less than most marine

Figure 1 Map showing the GOS route together with locations where marine isolates, sequenced as part of the Marine Microbial Genome Sequencing project, were collected. The red dots are the GOS sample sites that have been published to-date and the black dots are the marine isolates collection locations.

waters (Giovannoni *et al.*, 1990), which are usually at a density closer to 10^6 per ml, and the expectation was that these nutrient-limited conditions would yield a low picoplankton diversity.

While the Sargasso Sea surface samples were less diverse than soil or other complex environments, a substantial number of taxa were seen and it was far more diverse than had been expected. All in all, about 1800 species were estimated to be present based on the sequence relatedness, including nearly 150 previously unknown bacterial phylotypes. In addition, more than 1 million previously unknown genes were seen, including about 800 new bacteriorhodopsin genes (Venter *et al.*, 2004).

Several notable and unusual results from the Sargasso Sea work speak to both the values as well as the hidden traps of the metagenomic approach. First, and perhaps most notable, abundant *Shewanella* and *Burkholderia* were seen in one sample: abundant enough that nearly complete genomes were assembled from the shotgun sequencing data (Venter *et al.*, 2004). While it was not known at the time, these genera would never be seen in abundance again in any GOS sample. The reason for these results remains unresolved. The most convenient, and not unreasonable, explanation is that the sampling system was contaminated (DeLong, 2005). A more cautious view might be that it is due to a stochastic natural event (i.e., “natural contamination”). Given that members of both of these genera are known symbiotic inhabitants of the gut tracts of a wide number of different organisms, including marine and freshwater fish (Kikuchi *et al.*, 2007; Olivier-Espejel *et al.*, 2011; Tanu *et al.*, 2011; Ward *et al.*, 2009), it is also possible that the Sargasso Sea, with its low concentrations of bacteria might be easily overwhelmed by the passing excretion of gut contents into the sampling area by a marine fish: not an uncommon process in the marine environment (Ruby and Nealson, 1978). Finally, one might suppose that this could be the result of the flushing of the waste disposal system on the sampling boat, but this seems unlikely, as no enteric or other commonly encountered human-associated bacteria were seen. For the moment, and probably forever, these results remain enigmatic, and their importance has faded as subsequent sampling has moved them to the “rare and stochastic event” status. What remains important is the observation that several groups of bacteria were found in relative abundance, including *Pelagibacter* and *Prochlorococcus* types, along with several other groups known only by their 16S rRNA sequences. This was the first hint of a pattern that would repeat itself at nearly every marine surface site analyzed by the GOS expedition.

Of equal importance in the Sargasso Sea analyses were things that did not happen. Despite the abundance of *Synechococcus*, *Prochlorococcus*, and *Pelagibacter* types, based on the abundance of 16S rRNA gene sequences, in no case was it possible to assemble even a reasonably long scaffold from any of these three. That is, while the 16S rRNA data seemed to be saying that one species of each was present in abundance, the assembly data were saying that this species was sufficiently diverse that assembly into scaffolds was literally impossible. This was the first example of what was to be many such data sets to be seen for these three groups of microbes.

Finally, one very obvious potential limitation of this approach was noted in the Sargasso Sea work when combined with other genomic data. *Pelagibacter ubique* is according to 16S rRNA taxonomy an alpha proteobacterial phylotype, but contains a genome that is only about 1.2 Mbp, only a fraction of the size of most cultivated alpha proteobacteria (Giovannoni *et al.*, 2005). Thus, the approach to understanding the picoplankton via 16S rRNA is limited in its usefulness in this environment. Until one has an organism in cultivation, or its genome sequenced and sized, there is the distinct possibility that the 16S rRNA gene data provide limited information about the capacity and abilities of the particular taxon. Similar genome streamlining has been shown for two other bacterial groups, the *Flavobacteria* (Woyke *et al.*, 2009) and a gamma *Proteobacteria* group called SAR86 (Dupont *et al.*, 2012) for which both genomes were obtained via the sequencing of single cells.

One of the grand hopes of the GOS program was that function might be linked to identification of new groups of organisms, but in general, with assemblies being so limited, this was not achieved in the initial study. One notable exception to this was the identification of an archaeal 16S rRNA sequence connected via a scaffold to a gene that was similar to an ammonia oxidase (Venter *et al.*, 2004). This microbe has subsequently obtained in pure culture (Konneke *et al.*, 2005) and shown to be widely distributed in many marine environments (Francis *et al.*, 2005). Now called *Nitrosopumilis*, this group is known to be abundant in nearly all GOS samples, and in fact in many other environments around the world, as a major player in ammonia oxidation in many different environments. While the archaea in general are neither dominant nor diverse in the surface oceans, this particular group is both widespread and abundant.

Biodiversity Across Several Biomes and the PLoS Results:

The first attempts at “Global” data analyses were published in 2007, with a compilation of results beginning off the coast of Nova Scotia, and proceeding down the US coast, through the Panama Canal, to the Galapagos Islands, and ending in the equatorial Pacific. All in all, this data set consisted of 44 samples from 41 sites, including a few freshwater and hypersaline sites. The magnitude of this data set was such that patterns began to appear that could not be seen in the Sargasso Sea data (which were also included in this study) (Rusch *et al.*, 2007). For example the appearance of occasional “rare and stochastic events” was again seen, though with a resident population of microbes of 10^6 per ml, the sites were less susceptible to such events. Nevertheless, as a general rule, as more sites were examined, the “occasional” (often singular) appearance of a taxon as a dominant member was still seen, while the nearly continuous appearance of the three major players, and a number of other numerically dominant taxa became a general rule. A site without these phylotypes was unusual indeed.

Fragment Recruitment: Where do the GOS Sequences Come From?

Fragment recruitment (Rusch *et al.*, 2007) is a method whereby an entire genome can be “hybridized” in silico to the

Figure 2 Recruitment of GOS reads to a reference genome. The x-axis denotes the coordinates on the genome (in this case, *Candidatus Pelagibacter ubique* HTCC1062) and the y-axis denotes the percent identity of the match. Reads are colored by GOS samples that they belong to. Region in the box corresponds to a portion of the reference genome that does not recruit any GOS data.

GOS data, and the quantitative contribution of that genome to the surface picoplankton gene pool can be assessed (Figure 2). In the initial analysis via fragment recruitment, it was seen that only three genome types provided any significant fragment recruitment, even at the 50% identity level, and these were *Prochlorococcus*, *Synechococcus*, and *Pelagibacter*.

These three groups accounted for only about 15% of the total sequences, leaving a very large proportion of the GOS sequences unaccounted for by any of the genomes of cultivated and sequenced microbes that were tested (Rusch *et al.*, 2007). Thus, it appeared that the oceanic picoplankton were composed of a mixture of (mostly) unknown organisms, with very little genome similarity to any of the cultivated microbes. This overall view of biodiversity has become more solidified as the GOS data have been analyzed, and several hints have been provided by the data set:

First, several taxa were present at nearly every site, suggesting that there are a number of marine taxa, mostly uncultivated, that are very well adapted to life in the surface ocean. While they remain uncultivated, the identification of these “true picoplankters” is now slowly emerging through the abundance studies of the 16S rRNA gene content.

Second, in silico hybridization (fragment recruitment) of the GOS data set (i.e., the complete DNA sequence data with the “stochastic event” DNA samples removed) revealed no significant hybridization by DNA from any cultivated organisms other than *Synechococcus*, *Prochlorococcus*, or *Pelagibacter*. This rather remarkable result suggested that indeed, the picoplankton did not consist of microbes with which we were familiar, and that we really knew very little about the planktonic niche in terms of its taxonomic and functional biodiversity.

Third, as in the Sargasso Sea, assembly of the metagenomes from these environments generated only short contigs and scaffolds (with a majority of reads remaining unassembled), implying again, that there was substantial intraspecies diversity among these three major players. Is this again a property unique to these three genera, or will it be a common mode of adaptation in the marine surface ocean environment?

Functional Diversity of the GOS Sequences

The contribution of the published GOS data to our understanding of protein function and evolution has been significant. More than 6 million proteins were reported in the published GOS study (Yooseph *et al.*, 2007) – in the process more than doubling the number of known proteins. An

analysis of these proteins revealed thousands of novel protein families, and also showed that we have a long way to go in cataloging the protein universe, with protein family diversity being driven by a significant contribution from the microbial world. Many of the novel proteins appear to be of viral origin – a likely consequence of under-sampling of viral diversity. An analysis of protein families including RuBisCO, glutamine synthetase, phosphatases, proteases, and kinases, revealed novel subfamilies and substantial sequence diversity added by the GOS data. These data have added insights into the functional capabilities necessary for survival in the nutrient-limited open ocean environment.

Taxonomic and Functional Biodiversity of the Surface Ocean Picoplankton

The Marine Microbial Genome Sequencing Project (MMGSP)

The easiest explanation for the lack of fragment recruitment noted in the GOS study discussed above (*see* Fragment Recruitment: Where do the GOS Sequences Come From?) might be that the microbial genomes used for the hybridization were primarily nonmarine. In fact many of the genomes sampled were either from extremophilic archaea or medically important bacteria, neither of which might be expected to have gene complements abundant in the surface ocean. The Gordon and Betty Moore Foundation funded MMGSP was an international collaborative initiative whose goal was to sequence genomes of ecologically relevant microbes from the marine environment (Figure 1). As part of this project, we sequenced and annotated 137 genomes, and analyzed these together with genomes of previously published marine prokaryotes. Our collection included several strains of the “big three” (*Synechococcus*, *Prochlorococcus*, and *Pelagibacter*), as well as microbes from a wide variety of marine biomes.

Fragment recruitment was enlarged to include GOS data from a number of other sites, including the Indian Ocean. Remarkably, when the fragment recruitment exercise was finished, the results remained virtually unchanged. The top recruiters were still the “big three,” and virtually no increase in recruitment to other groups was seen with the addition of the MMGSP genomes (Yooseph *et al.*, 2010).

The results from genomic, metagenomic, and 16S rRNA analyses (Yooseph *et al.*, 2010) lend credence to our view of the biodiversity of marine surface picoplankton: there appear

to be a few (i.e., 10–20) dominant and cosmopolitan taxa that represent the true picoplankton in the oceanic surface waters, and of these, only three have been cultivated. And for most of the others, reference genomes are not yet available. Thus we remain “in the dark” with regard to the biodiversity of this group, which we refer to as the “true picoplankton.”

Looking at the properties of the GOS data set, some predictions of what the true picoplanktonic population is composed of can be made, and the conclusions reached by this approach provide a picture that is somewhat different from the traditional view: The picoplankton is a group of very small microbes (with reduced genome size) that have given up many of their complex regulatory abilities, and have adapted to the marine surface niche by staying small, growing slowly, and being incapable of adapting to nutrient additions by increasing their growth rate and blooming (Yooseph *et al.*, 2010). These are nonmotile and nonchemotactic aerobes, with major reductions in genome size and metabolic abilities.

Some recent results support this view of the oceanic picoplankton. Woyke *et al.* (2009) recently used single-cell genomics methods to sequence and assemble the genomes of two *Flavobacteria* cells (MS024–2 A and MS024–3 C). These genomes showed recruitment to the GOS data supporting the notion that they are cosmopolitan and numerically abundant members of the marine picoplankton. Both genomes showed substantial genome streamlining, with genomes of these two being only 1.9 and 1.5 Mbp, respectively, much less than the 6.1 and 2.9 Mbp genomes of two cultivated *Flavobacteria* isolates (Woyke *et al.*, 2009). In addition, analysis of the gene content suggested that they were adapted to a narrow (focused) metabolic niche: one that might include algal interactions, perhaps as attached forms.

In another study utilizing single-cell genomics and metagenomic assemblies, Dupont *et al.* (in press) showed similar results for four assembled genomes of SAR86-like microbes. Fragment recruitment was significantly higher than seen with the *Flavobacteria* genomes obtained using single-cell genomics, and, as with the *Pelagibacter* genomes, when the required identity level was relaxed from 90% to 50%, fragment recruitment increased dramatically, suggesting to the authors that there is a broad diversity within this group that is yet to be discovered (Dupont *et al.*, in press). The two of the four genomes that are nearly complete (SAR86A and SAR86B) have genomes of 1.25 and 1.7 Mbp, respectively, considerably smaller than other gamma *Proteobacteria* that usually sport genomes of about 5 Mbp. Metabolic mapping of the genome indicates that SAR86 types are aerobes that may be focused on the degradation of lipids and carbohydrates acquired by Ton-B dependent outer membrane receptors. As with both the *Flavobacteria* obtained using single-cell genomics, and *Pelagibacter*, this heterotroph appears to have a narrow metabolic set of preferences, thus avoiding competition via specialization for unique resources.

The GOS approach has allowed the formulation of a particular view of the world’s surface picoplanktonic population, which the authors will discuss below. It includes almost exclusively organisms that, until recently, were not known, and many of which are still not cultivated (and many that are not yet sequenced). Based on 16S rRNA analysis and fragment recruitment results, one can speculate that another 10–20 microbial groups of microbes will be required to have a good

picture of the diversity of the abundant and cosmopolitan members of the surface picoplankton.

While we now have some sense of the functional adaptation of the picoplankters, the situation remains at best incomplete. With genomes of two photoautotrophs (*Synechococcus* and *Prochlorococcus*) and three chemoheterotrophs (*P. ubique*, *Flavobacteria* spp., and SAR86-like), we can assemble some traits that appear to be common among them with the expectation that this situation will change as more members of the picoplankton are characterized. These traits include: (1) genome reduction; (2) low GC content; (3) lack of or decrease in many functional and regulatory genes, including those involved with transcriptional regulation, energy linked transport systems, efflux systems for toxic metals and drugs, chemotaxis, motility, and quorum sensing, protein secretion, siderophore synthesis and uptake, and anaerobic metabolism. In addition, CRISPRs are notably absent or reduced.

This is a far different picture of the marine picoplankton than anything we imagined before GOS. In this nutrient limited world, the plankters are well adapted, with very little taxonomic diversity, but substantial intrataxon diversity – diversity that challenges the assembly of genomes of these key species.

Given the reduced genome sizes of the picoplankters, the cells are, as expected, quite small. Thus, while they constitute the preponderance of 16S rRNA gene sequences (and thus genomes), they may have far less impact at the level of biomass. For example, some strains of *P. ubique* have cells that are only 1/1000 the biomass of an *E. coli* sized microbe (Giovannoni *et al.*, 2005), so if they are 10^5 ml^{-1} and a *Vibrio* species is at 10^2 ml^{-1} , the relative amount of biomass is approximately the same! Without very deep sequencing, the *Vibrio* cells will not be seen by our shotgun sequencing methods. If one imagines that conditions change to favor growth of the *Vibrios*, then their ability to bloom in response to changes in available nutrients could allow them to rapidly become the dominant biomass in a given oceanic niche, as has been hypothesized and observed by many workers (Hunt *et al.*, 2008; Preheim *et al.*, 2011; Thompson *et al.*, 2005). Given the GOS data set, we conclude that this has not happened in any of our sites, but believe that such phenomena are an integral part of marine biology, and must be part of the ecological strategies of the microbes that are in most of our culture collections. One example of this is the report of a bioluminescent zone (milky sea) off the coast of Somalia, proposed to be a bloom of luminescent *Vibrios* at a concentration of 10^7 ml^{-1} or more (Nealson and Hastings, 2006). Such a bloom could be the natural consequence of the crash of an algal bloom, leading to abundant surface nutrients, and a dominant bloom of light-emitting microbes. Similar nutrient enrichment(s) could stimulate growth of the more familiar cultivated microbes via providing niches such as marine snow (Grossart *et al.*, 2006), stomachs of marine invertebrates and vertebrates (Roeselers *et al.*, 2011; Ruby and Nealson, 1978; Tanu *et al.*, 2011; Ward *et al.*, 2009; Wu *et al.*, 2010), or niches associated with symbiosis or parasitism (Cai *et al.*, 2006). This view is in concert with a recent presentation of marine microbial diversity by Lauro *et al.* (2009) in which it was proposed that the marine picoplankton are essentially a continuum of metabolic types, ranging from ultra-oligotrophs to

“bloom and bust” coprophytes. This is a view that fits well with our own view of biodiversity, although our view is that the true picoplankters (based on abundance and continuity of appearance) do not include the coprophytes, which come and go, but were rarely seen in the GOS sampling program.

Of importance in this discussion is the fact that the GOS data have to this point, examined only those microbes on the smallest filter size – the picoplanktonic populations. Particle associated microbes and large cells may well constitute a major part of the marine biomass, but we maintain that they are a reflection of other niches, and not a part of the “true picoplankton.”

The “Faces of Biodiversity”

Putting all of this together, then, the biodiversity of the surface ocean takes on a number of faces, some of which are not yet clearly articulated. The first is that of the true picoplankton, as we call them: the small, reduced genome, reduced function, low biomass microbes that seem very well suited to the nutrient limited surface ocean environment. While we have a sense of the taxonomic diversity of these microbes, we have only a beginning knowledge of their functional diversity. A second area of the unknown is the extent of intragroup diversity, and whether or not such diversity will be also seen in the other true picoplankton.

The second “face” of biodiversity is that of the more familiar cultivated strains of which we now have more than 200 genomes sequenced and in hand. These microbes, for the most part look familiar to us, and do not provide the intragroup diversity seen in the true picoplankton. However, the extent of their functional diversity remains unknown, and their true niches within the marine ecosystem(s) remains mysterious. The niches inhabited by marine luminous *Vibrios* include light organs and stomachs of fishes and squids, marine snow, and particulate matter, fecal pellets, and perhaps more (Nealson and Hastings, 2006), and with the exception of the fish and squid symbioses, whether or not any or all of these environments are taxon-specific is not known. One could easily hypothesize that such niches provide a need for intragroup variation of these types that could be as extreme as that seen in the true picoplankton. The difference, of course, is that microbes in this group are capable of rapid growth and the maintenance of nearly clonal populations, something that would seem difficult among the true picoplankton.

We close this discussion of picoplankton diversity with a brief discussion of a recent paper by Konstantinidis *et al.* (2009) in which populations of deep sea microbes were analyzed for taxonomic and functional diversity. The environment under study was the deep water off Hawaii, where the surface waters look remarkably like the GOS sites discussed. However, the deep waters are substantially different – in fact, they resemble an environment that is populated by species of the type consistent with our “second face” – microbes that we expect to be able to grow, and which might be expected to be found in more nutrient-rich niches. In contrast, this environment is notable because it is dark, nutrient poor, and presumably so depauperate that the surface ocean true picoplankton are not able to survive here!

It is our thesis that the diversity of this deep ocean site is due to the bacteria-laden particles arriving at the site, along with the oceanic eukaryotes, which may be hosts for such microbes, and contribute to their small but continuous population(s) in the deep sea. This view places the eukaryotes squarely in the center of prokaryotic evolution, a place that is not unreasonable, but one that is also only a hypothesis at this time – one that deserves attention and testing.

Conclusions

The GOS program, begun in 2003 and still in progress, has provided a view of the surface ocean microbial communities, with samples collected by the *Sorcerer II* Expedition and Collaborator Cruises from more than 200 sites from around the world. The emerging view of surface ocean microbiology is in harmony with other metagenomic studies of the ocean, and, while not the last word on picoplankton biodiversity, paints a picture of the oceanic plankton that is notably different from the paradigm that was accepted only a few years ago. A few “lessons” serve to highlight the bulk of these differences: (1) the taxonomic diversity of the surface ocean is remarkably low, with just a few (probably 20 or less) numerically dominant taxa; (2) while only three of these taxa have members currently in cultivation, for these three, the intragroup diversity is extremely high, leaving us with a niche that is characterized by a few dominant taxa that are within them, extremely diverse at the genome level; (3) the oceanic DNA sequences reveal a collection of genes that have no strong genomic sequence relationship to the gene content of many cultivated and sequenced bacteria and archaea; and (4) of the few examples of the dominant and cosmopolitan picoplankters that have been sequenced, all appear to have undergone extreme genome reduction, so that while they can be placed in familiar taxonomic clades, their genomic content renders them far different from their phylogenetic brothers and sisters.

However, to date, only a few marine picoplankters have been sequenced, and as these groups are identified and characterized, our appreciation of the metabolic diversity of the surface picoplankton will continue to grow. With regard to this, a few of the abundant and cosmopolitan picoplankters are now being analyzed using a combination of metagenomics and single-cell genomics. The bottom line of these analyses, for the present, suggests that the surface oceanic picoplankton are a group of microbes from different taxa, which are highly adapted to the nutrient limited conditions of the ocean. In contrast, most of the cultivated and sequenced counterparts are capable of “boom and bust” ecology, and occasionally are found in high numbers (as blooms), but were rarely found in abundance in the GOS sites examined. This suggests that the ecology of these readily cultivated forms is distinctly different from the abundant and cosmopolitan picoplankters whose genes dominate the GOS data set.

Glossary

Bacteria Used as equivalent term for prokaryotes (Eubacteria + Archaeobacteria); now frequently used as a synonym for Eubacteria.

Chemoautotrophy (chemotrophy) Energy metabolism exclusively based on the oxidation of inorganic compounds and the energy-requiring reduction of CO₂ for the generation of organic matter.

Cyanobacteria A large group within the Eubacteria with chlorophyll *a* and oxygenic photosynthesis; formerly known as “blue-green algae.”

Methanogenic bacteria Anaerobic archaeobacteria that convert CO₂ + H₂ or acetate into CH₄.

Nitrogen fixation The ability to fix atmospheric N₂ into organic N via ammonia; a widespread ability among several unrelated groups of prokaryotes.

Phagotrophy Feeding on particulate matter occurring exclusively among the eukaryotes.

Phototrophy Energy metabolism based on light energy; photosynthesis also means that the gained energy is also used for the reduction of CO₂ to organic matter.

Prokaryotes (bacteria) Organisms that are not eukaryotes (archaeobacteria + eubacteria).

Protists Unicellular eukaryotes (protozoa + protophytes)

Sulfur bacteria Bacteria that depend on the chemotrophic or phototrophic oxidation of reduced sulfur compounds for energy generation.

Definition of Microbes

Microbes are defined mainly by their size; most are unicellular, but some form colonies which may be macroscopic. Some “microorganisms” even exceed the size of the tiniest animals (metazoa). Taxonomically, microbes include the prokaryotes or bacteria (the eubacteria and the archaeobacteria) (Dworkin *et al.*, 2006) and members of various unrelated eukaryotic groups, together referred to as protists meaning protozoans (including some fungi-like organisms) and protophytes (unicellular algae) (Hausmann and Hülsmann, 1996). Contemporary understanding of phylogeny (Figure 1) reveals that biological diversity is largely microbial: In this representation, multicellular organisms (plants, animals, fungi, and macroscopic algae) appear as minor and evolutionarily recent additions to the “tree of life.” This is also reflected perhaps by the fact that except for vascular plants (which are largely responsible for primary production on land) biogeochemical cycling of elements is mainly the result of microbial activity.

Although microbes have been defined in terms of size, it should be emphasized that the size range of microbes is immense. The smallest, free-living bacteria measure <0.5 μm and the largest protozoan cells measure >1 mm (some foraminiferan species measure >1 cm). The size range of microbes, 1 μm to 1 mm (a factor of 10³ or a factor of 10⁹ in terms of volume), approximately equals that of all vertebrates (guppies to whales).

Even so, some general properties of microbes that relate to their relatively small size can be identified. Among these, the most important is a high “rate of living” – that is, high weight-specific metabolic rates and high growth and reproduction rates. When organisms spanning a wide size range are compared, weight-specific metabolic rates tend to decrease proportionately to the one-fourth power of body weight, and generation times tend to increase proportionately to

Figure 1 The “universal tree” based on rRNA sequencing. Microbes include, in addition to the prokaryotes (Archaeobacteria and Eubacteria), most major eukaryotic groups. For clarity, only a few major groups are included in the tree. Only animals, fungi, plants, and a few (omitted) algal groups represent macroscopic, multicellular organisms; all other organisms are “microbes.”

the three-fourths power of body weight. Under optimal conditions the generation (doubling) time of bacteria may be as short as 20 min and unicellular eukaryotes typically have generation times between 4 and 24 h. Consequently, a relatively small microbial biomass may be responsible for a relatively large part of the flow of energy and materials in ecosystems. Certain microorganisms may in some

circumstances form conspicuous accumulations of biomass in nature, but usually they are macroscopically invisible constituents of, for example, soils and seawater. However, due to their high weight-specific metabolic rates they dominate as agents of chemical transformations in the biosphere.

There are other characteristics of being small. Uptake of solutes from the surroundings (e.g., dissolved oxygen or organic substrates) is by molecular diffusion, a fact that is important in shaping microbial communities and which imposes constraints on physical transport rates. Due to their small size and low swimming velocities, microorganisms live at “low Reynolds numbers”; this implies that motility depends on viscous rather than on inertial forces. Many properties relating to motility and motile behavior of microorganisms therefore appear counterintuitive (Fenchel *et al.*, 1998).

However, functional diversity of microorganisms is more evident than their similarities. It is therefore expedient to discuss prokaryotic and eukaryotic microorganisms separately.

Prokaryotes (Bacteria)

Principal Properties of Bacteria

The prokaryotes include two major groups of life: the archaeobacteria (sometimes referred to as archaea) and the eubacteria (sometimes referred to as bacteria), which are differentiated by numerous genetic and biochemical traits. Structurally and functionally, however, they show so many similarities that it is appropriate to discuss them together and to retain the term bacteria (= prokaryotes) for these organisms that are not eukaryotes. In contrast to eukaryotic cells, bacteria do not have a cytoskeleton and almost all bacteria are enclosed by a rigid cell wall (Madigan, 1997). These features result in certain general properties. The limitation of diffusional solute transport from the surrounding water and within the cell typically constrains bacterial size to 1 or 2 μm . Certain giant bacteria (mainly among cyanobacteria and sulfur bacteria) measure 5–10 μm or more and in one case almost 1 mm, but these giant bacteria usually include a large internal vacuole. Bacteria take up only low molecular-weight solutes from their surroundings. Bacteria that depend on high molecular-weight polymeric compounds as a source of energy and organic carbon must first hydrolyze their substrates extracellularly, using membrane-bound enzymes, before the resulting monomers can be transported into the cell. This transport may be “passive” (facilitated diffusion) or “active” (ATP dependent). The small size of bacteria means that they can exploit and grow in extremely dilute substrate solutions (e.g., approximately 50 nmol l^{-1} of amino acids or glucose).

Two additional properties explain the important role of bacteria in the biosphere; these apply to bacteria as a group rather than to individual species. One is that many bacteria are “extremophiles”: Extreme thermophilic bacteria live at temperatures $>80^\circ\text{C}$ (or $>100^\circ\text{C}$ under hyperbaric pressure); extreme halophiles may grow in saturated brine; acidophilic and alkalophilic bacteria occur at a pH <2 and >10 , respectively; and some bacteria tolerate toxic metal ions (e.g., copper and zinc) in millimolar concentrations. A variety of habitats (hot springs, brines, subsurface, etc.) are inhabited

exclusively by prokaryotes. Many natural habitats lack oxygen (e.g., aquatic sediments, stratified water bodies, water saturated soils, or even the interior of soil aggregates and detrital particles) because diffusive supply of O_2 cannot meet the demand for aerobic microbial respiration. Many bacteria have an anaerobic energy metabolism and they are practically the only inhabitants of anoxic environments except for a few species of anaerobic protozoa. It seems that bacteria have only one absolute requirement for metabolism and growth: liquid water. Active “terrestrial” bacteria (and other microorganisms) are therefore confined to water films surrounding soil particles, leaf litter, plant surfaces, and the like.

Another collective property of bacteria is their metabolic diversity, which far exceeds that found among eukaryotes. Metabolism of bacteria includes processes such as the oxidation and reduction of inorganic sulfur, nitrogen, iron, and manganese compounds and the production and oxidation of methane. Some bacteria can grow using hydrocarbons as a substrate. Some phototrophic bacteria use H_2 , H_2S , or Fe^{2+} as electron donors (rather than H_2O as in algae, plants, and cyanobacteria) for the reduction of CO_2 and many bacteria can assimilate atmospheric nitrogen. These are all fundamental (but exclusively bacterial) processes in the biosphere. There is a limited number of types of energy metabolism that seem evolutionary conserved and a few of these have been taken over by eukaryotes. In addition, all natural and many xenobiotic polymers can be hydrolyzed by at least one type of bacterium (Falkowski *et al.*, 2008).

Metabolic Diversity of Bacteria

It is convenient to distinguish between dissimilatory (energy and catabolic) metabolism and assimilatory (anabolic) metabolism, although the distinction is not always sharp. Heterotrophic bacteria typically use a given organic substrate for dissimilation and also as a carbon source for growth, whereas autotrophic bacteria must use energy gained in dissimilatory metabolism for the reduction of CO_2 . Energy generation and growth are coupled because most energy generated is used for the synthesis of macromolecules (DNA, RNA, and proteins), for active transport of substrates into the cell, and sometimes for assimilatory reductions. In microorganisms there is therefore typically an almost linear proportionality between energy generation and reproductive rate. Here, the concentration is on energy metabolism because it provides an overview of the functional diversity and roles of bacteria in the biosphere, notwithstanding that the synthesis of bacterial biomass is also an important process in terms of providing a basis for phagotrophic food chains (Fenchel *et al.*, 1998; Zehnder, 1988).

Table 1 presents a (simplified) overview of major types of bacterial energy metabolism. Different types of microbial processes predominate in different habitats according to the chemical environment (availability of substrates and electron acceptors), to thermodynamics (energy yields of the different processes), and to certain physiological constraints. Many of the listed processes are interdependent in nature in that one functional type of bacteria requires the presence of other types of bacteria.

Table 1 Principal types of energy metabolism in bacteria

Fermentation	Anaerobic processes in which (organic) molecules are dismutated. No external electron acceptor, redox equilibrium; low energy yield. Principal end products (of carbohydrate fermentation): acetate and $\text{CO}_2 + \text{H}_2$, but many fermentation types are incomplete and metabolites then include other low molecular-weight fatty acids and alcohols.
Respiration	Use of an external electron acceptor, electron transport phosphorylation.
Aerobic respiration	O_2 as terminal electron acceptor. A variety of organic substrates are used by different heterotrophs. Chemoautotrophs use O_2 to oxidize various inorganic substrates (reduced S, N, Fe, or Mn compounds and H_2 and CH_4). Aerobic respiration provides the highest energy yield of any known metabolic process.
Anaerobic respiration	Use of external electron acceptors other than O_2 . Denitrifiers use NO_3^- (reduced mainly to N_2 or N_2O) to oxidize a variety of organic compounds and reduced S compounds (but not CH_4). A recent discovery is that some bacteria can oxidize ammonia with nitrite with principal end product being N_2 . Sulfate reducers produce H_2S while oxidizing especially H_2 or low molecular-weight fatty acids. Iron and manganese reducers use Fe^{3+} and Mn^{4+} for the oxidation of substrates.
Methanogenesis	Methanogenesis is found only among certain anaerobic archaeobacteria. Acetoclastic methanogens dismutate acetate into $\text{CO}_2 + \text{CH}_4$; CO_2/H_2 methanogens produce CH_4 from $\text{H}_2 + \text{CO}_2$. Some methanogens can also produce methane from reduced C-1 compounds (e.g., methanol).
Phototrophy	Phototrophs use light energy for generation of ATP and (with an external electron donor) for the reduction of CO_2 to organic compounds. Oxygenic phototrophs (cyanobacteria) use H_2O as electron donor and produce O_2 as metabolite. Anoxygenic phototrophs (several groups of bacteria) use H_2S , H_2 , or Fe^{2+} as electron donors, thus producing $\text{S}^0/\text{SO}_4^{2-}$, H_2O , or Fe^{3+} . Some anoxygenic phototrophs have lost the ability of CO_2 reduction, but can generate ATP in the light; these bacteria have proven to be important in marine plankton. Some other bacteria use the so-called opsins – related to the visual pigments in eukaryotes – for energy conservation in the light.

Under oxic conditions, aerobic bacteria completely dominate in accordance with the fact that oxygen respiration yields more energy than any other metabolic process. Bacterial diversity in aerobic habitats is to a large extent due to differential abilities to hydrolyze different polymers, but most species are capable of complete mineralization of organic monomers to CO_2 , H_2O , and mineral N or of the complete oxidation of reduced inorganic compounds.

Anaerobic bacteria, by contrast, are specialists, and a complete mineralization under anaerobic conditions requires several physiological types of bacteria. Fermenting bacteria play a key role in anaerobic habitats because they are (nearly) the only anaerobes capable of hydrolyzing polymers. The complete fermentation of, for example, carbohydrates (to acetate + $\text{CO}_2 + \text{H}_2$) is thermodynamically possible only if the ambient H_2 tension is low (approximately $< 10^{-4}$ atm). Low H_2 tension results from the activities of H_2 -consuming bacteria, notably sulfate reducers and methanogens. This syntrophic interspecies H_2 transfer is an essential feature of anaerobic habitats. In general, metabolic end products of fermenting bacteria serve as substrates for anaerobic respirers. The type of respiration that will dominate depends on the availability of external energy acceptors and on the energy yield of the different types of oxidation. After aerobic respiration, nitrate respiration is the energetically most favorable process, but its quantitative importance is often limited by the availability of NO_3^- . When nitrate becomes exhausted, Mn^{4+} followed by Fe^{3+} are the electron acceptors of choice; when these are exhausted sulfate respiration prevails (Figure 2). In marine sediments, sulfate reduction is typically the dominant process because of the high concentration of SO_4^{2-} in seawater (about 25 mM compared with about 250 μM O_2 at atmospheric saturation; the capacity for oxidation of organic matter through sulfate reduction is approximately 200 times more than through O_2 reduction and so, in contrast to O_2 , SO_4^{2-} supply is not rapidly exhausted).

Only when sulfate is depleted will methanogenesis be quantitatively important; this only at considerable depth in marine environments, and is more important, for example, in lake sediments. In anaerobic habitats, the microbial processes are therefore spatially or temporally structured; for example, when moving downward from the surface of sediments, O_2 , Mn^{4+} , Fe^{3+} , and SO_4^{2-} are depleted sequentially. The reduced end products of anaerobic metabolism diffuse upward and are eventually reoxidized by O_2 (or NO_3^-) by chemoautotrophic bacteria residing at the aerobic–anaerobic interface. The complex interactions between different types of bacteria in anaerobic habitats and at the anaerobic–aerobic interface are often referred to as a “food chain” by microbiologists. It differs fundamentally from phagotrophic food chains, however, in that the organisms do not feed on each other but rather that one functional group of bacteria utilizes the metabolites of another functional group.

Hydrolysis of polymers is often the rate-limiting step in mineralization. Some substrates are inherently difficult to hydrolyze, notably the ligno–cellulose complexes of woody tissue and many other natural plant compounds such as phenols, waxes, tannins, and cork substances (whereas pure carbohydrates, such as cellulose and hemicelluloses, are relatively rapidly degraded under aerobic and under anaerobic conditions). Hydrolysis may also be limited by the availability of mineral nutrients (N and P) that are assimilated (“immobilized”) by bacteria during decomposition of mineral-poor substrates (such as most plant tissue and litter). Crude oils (which contain a mixture of normal and branched paraffins, aromatic hydrocarbons, and other compounds) are degraded by a variety of aerobic bacteria and anaerobically by nitrate or sulfate reducers; the rate of crude oil mineralization is generally limited by the access to mineral nutrients, especially N and P. Otherwise, easily degradable monomers (e.g., amino acids) may bind to clay minerals or humic substances to become temporarily or permanently inaccessible to bacterial

Figure 2 A biosphere model incorporating different microbial respiration processes. Oxygenic phototrophs use light energy to produce O_2 and organic matter ($[CH_2O]$); this represents the chemical potential that maintains the biosphere. Microorganisms derive energy by redox processes involving oxidants (left) and reductants (substrates) (right). The standard potential of the half-cell processes decreases from above so that the oxidant has to be situated higher than the reductant if the process is to be thermodynamically possible. Oxidations of organic matter may take place stepwise (e.g., first by sulfate reduction and the resulting sulfide can subsequently be oxidized by O_2). A few processes (e.g., N_2 oxidation) are not realized due to kinetic constraints. Data on free energy changes are not precise under physiological conditions because the processes do not necessarily occur under standard conditions and because only a part of the potential energy is conserved as ATP; however, the energetic hierarchy of the processes holds.

attack. Humic substances are complexes consisting mainly of aromatic rings deriving from lignin, quinones, and phenols. Humic substances are very resistant to microbial attack and their rate of turnover in nature must be measured in centuries.

Some polymers are not, or are only very slowly, degraded under anaerobic conditions. This applies to, for example, lignin and some other plant compounds. Anoxia in conjunction with a low pH, such as found in moors and swamps, strongly limits mineralization, and peat, in which the original structure of plant material is often preserved, accumulates. Even in marine sediments, a certain fraction of the organic input is not mineralized but fossilized as kerogen in sedimentary rocks. Peat is eventually (over geological time through abiologic processes) transformed into lignite and coal. Large accumulations of organic matter in marine deposits may eventually transform into crude oils and natural gas.

Roles of Bacteria for Element Cycling in the Biosphere

The single most important role of bacteria in the biosphere is the degradation and mineralization of organic matter produced by (mainly eukaryotic) phototrophs. In some habitats, however, primary production by prokaryotic phototrophs is also significant.

Mineralization processes are often complex due to spatial and temporal heterogeneity, limiting physical transport rates, and kinetic and physiological constraints. This complexity is especially evident where anaerobic processes are important as in sediments. There are considerable differences between major habitat types and these will be discussed separately in the following four sections.

The Water Column of Oceans and Lakes

Prokaryotic oxygenic phototrophs play a specific role in the water column. Thus, the unicellular, 1- μ m-large *Synechococcus* cells are ubiquitous in lakes and in seawater, typically occurring at densities of approximately 10^5 ml^{-1} . Their role in primary production (relative to that of eukaryotic phototrophs) is especially important in oligotrophic oceanic waters where it may account for 30–70% of the total production. The tiny *Prochlorococcus* has more recently been shown to be important in the deepest parts of the photic zone (> 100 m) in oceanic waters. Blooms of large colonial filamentous cyanobacteria (e.g., *Trichodesmium*) occur periodically in some marine waters; the organism is capable of N_2 fixation and is thus favored by P-rich but N-depleted water masses. Macroscopically conspicuous blooms of various species of colonial cyanobacteria are common phenomena in eutrophic fresh waters (Falkowski and Knoll, 2007; Harris, 1986).

Aerobic heterotrophic bacteria, however, are the most important group of prokaryotes in the water column. They typically occur in numbers ranging between 5×10^5 and 5×10^6 cells ml^{-1} constituting a volume fraction in seawater ($\sim 10^{-6}$) comparable to that of other important biotic components (e.g., phytoplankton). Their relatively constant numbers imply that they are controlled by grazing (mainly by protozoa) and they are also subject to viral attack, and their turnover is relatively rapid (varying from < 1 to several days).

Bacteria depend on dissolved organic compounds which again derive from several sources. The most important one seems to be the passive excretion of photosynthate from phytoplankton cells; it is estimated that between 5% and 40% of primary production is lost in this way from algal cells to become mineralized by bacteria. Other sources include allochthonous material (e.g., runoff from land), degradation of macroalgae, and "sloppy feeding" by zooplankton. Dissolved organic matter in natural waters covers a wide range of molecular size from monomers (amino acids and monosaccharides) to colloidal matter. Small monomers have a rapid turnover (sometimes < 1 h) and occur at very low concentrations (nM range) due to efficient bacterial utilization. Larger molecules are utilized much more slowly due to their lower diffusion coefficient and because their utilization requires extracellular hydrolysis. Some macromolecular compounds (humic substances) are very recalcitrant; they have a very low turnover rate, but constitute the bulk of dissolved organic matter.

The fact that a relatively large part of primary production is channeled via dissolved organic matter to bacteria, which then enter phagotrophic food chains, has been termed the microbial loop (Figure 3). The relative amount of the primary production which is channeled through the microbial loop compared with the "classical plankton food chain" (large phytoplankters $\rightarrow$ copepods $\rightarrow$ planktivorous fish $\rightarrow$ carnivorous fish) depends on circumstances. The classical food chain is

Figure 3 The “microbial loop” in the water column. A fraction of the photosynthate is lost from phytoplankton cells to become incorporated into bacteria, which then enter phagotrophic food chains.

particularly favored by large or periodic influx of mineral nutrients (such as in upwelling zones); otherwise, the microbial loop seems to dominate in terms of carbon flow (Fenchel, 1987).

Special microbial biota are associated with aggregates (“marine snow”) which consist of different types of particles (diatom frustules, fecal material from plankton organisms, etc.) held together by colloidal material. They form in the water column where they constitute approximately 10% of non-living organic matter; they eventually sink to the bottom and become the basis for benthic life. They are, however, rapidly colonized by bacteria (and other microorganisms) and so a substantial part of the organic fraction is mineralized while still suspended in the water column; it has been estimated that 75–80% of the organic matter is lost during a passage of 2000-m depth.

Aquatic Sediments

The most important property of sediments is that vertical solute transport depends on molecular diffusion. Organic material – produced in the water column – sediments and is in part mixed into the sediment through the activity of burrowing animals. The aerobic metabolism of microbes and animals deplete O_2 at a certain depth, depending primarily on the input of organic material. In shallow-water sediments, anoxia typically prevails a few millimeters beneath the surface; at greater water depths the oxic zone typically measures several centimeters. Beneath the oxic–anoxic interface (the “chemocline”) mineralization is anaerobic. As previously explained, various other electron acceptors are used by bacteria for the oxidation of their substrates (Figure 2). In marine sediments sulfate reduction dominates and, in shallow offshore sediments, may be responsible for more than 50% of the terminal mineralization. The resulting metabolite, hydrogen sulfide, is thus produced in copious amounts. Some of it combines reversibly with iron to form black FeS , but most diffuses upward to become reoxidized by chemoautotrophic sulfur bacteria at the chemocline and therefore a major portion of the O_2 uptake of marine sediments is due to the reoxidation of microbially produced sulfide. Some of the ferrous sulfide reacts (abiotically) with sulfide to form the somewhat more stable pyrite (FeS_2), which appears as a type of fossil fuel in sedimentary rocks.

In sulfate-poor freshwater systems methanogenesis plays a major role as the terminal anaerobic mineralization process.

Some of the CH_4 formed is reoxidized aerobically in the sediment surface or in the water column; since CH_4 (in contrast to sulfide) has a low solubility, much escapes to the atmosphere via ebullition.

In productive shallow waters the anaerobic zone may reach the surface of the sediments. This is macroscopically visible as a white cover of chemoautotrophic sulfur bacteria (they owe their color to intracellular elemental sulfur). If the sediments are exposed to light, the surface may instead be dominated by a purple layer of phototrophic sulfur bacteria. In stratified water bodies (such as thermally stratified lakes or where there is a salinity difference between the surface and deep waters), vertical, turbulent transport of dissolved O_2 from the surface layers to the deep layers is prevented. The chemocline may then extend above the sediment surface and into the water column. The phenomenon is common (at least seasonally) in deep, productive lakes and in fjords with a sill; the largest permanent anoxic water body on the Earth is the Black Sea, which is everywhere anoxic and sulfidic below 150- to 200-m depth (Fenchel *et al.*, 1998; Konhauser, 2007).

Terrestrial Soils

The microbial life of soils differs in many ways from that of aquatic sediments. The chemical composition of soil organic matter differs because it mainly derives from vascular plants and therefore includes large amounts of structural polymers (especially lignin and cellulose). Vascular plant tissue is very poor in mineral nutrients; C:N ratios typically exceed 60, which affects the microbial nitrogen cycle of soils. Another important feature is that soils represent a complex matrix that includes air-filled spaces. Since diffusion coefficients are approximately 10^4 times higher in air than in water, soils are not anaerobic throughout, although anaerobic microniches may occur within individual waterlogged soil particles, and therefore anaerobic microbial processes do occur. In general, the biological activity of soils exceeds that of aquatic sediments reflecting the higher input of dead organic matter. Microbial activity in soils affects soil fertility and some processes (e.g., CH_4 oxidation and denitrification) affect element cycling on a global scale.

The overall important, and variable, factor controlling soil microbial activity – qualitatively and quantitatively – is water content. Fungi (ascomycetes and basidiomycetes) are better adapted to water stress and their hyphae can penetrate air-filled spaces; in soils and litter they are therefore important rivals to bacteria as primary decomposers. Certain bacterial groups (including the spore-forming Gram-positive bacteria and the fungi-like actinobacteria and myxobacteria) are better adapted to water stress than other types of bacteria and thus play a relatively larger role in soils. For a given type of soil there is an optimum water content for microbial activity: A very low water content prevents microbial activity; when a large fraction of pores are water filled, anoxic conditions are more widespread, thus inhibiting aerobic processes. Water contents affect, for example, soil nitrogen cycling: low water contents favor ammonia oxidation (nitrification, an aerobic process), whereas high water content favors denitrification (an anaerobic process leading to loss of reactive N from the soil).

The highest microbial activities are found within the root zone (rhizosphere). Microbes (in part directly attached to plant roots) exploit dissolved organic material, which is excreted

from the roots. They also form the basis for protozoan grazing. In addition to direct microbe–plant interactions (such as symbiosis with N_2 -fixing bacteria), microbial activity has a profound indirect effect on soil fertility through its effects on mineral nutrient cycling (Coleman and Crossley, 1996).

Extreme Environments

The microbiology of extreme environments (here including hyperthermal and subsurface habitats and brines) has recently drawn considerable interest. Studies have expanded our knowledge of microbial diversity (especially of thermophilic archaeobacteria) and led to the discovery of novel microbial communities; the potential for isolating microbes producing industrially useful enzymes has also spurred interest in extreme environments.

Microbial mats are communities that develop in environments with no or little animal grazing and disturbance. These are complex biota that include a great variety of interacting physiological types of prokaryotes and in some cases also include eukaryotic microbes. Cyanobacterial mats develop in illuminated thermal springs and brines (salterns); when undisturbed, they develop laminated deposits (stromatolitic mats) over centuries that may attain a thickness of several meters, although almost all biological activity is concentrated in the upper few millimeters. They are a modern analog to Precambrian stromatolites, which seem to have represented the dominating shallow-water biota for approximately 2.8 billion years of the Earth's history; they almost disappeared from the geological record in the past 600 to 700 million years (My), when metazoans made their appearance. Cold or hot seeps of sulfidic water support mats of chemoautotrophic sulfur bacteria. These biota – well known from not only deep-sea hydrothermal vents but also occurring elsewhere – are interesting in that their energy support (sulfide, methane, and reduced Fe) derives from geothermal processes rather than from solar energy via photosynthesis (however, the oxygen, which is necessary for exploitation of these energy sources, derives from oxygenic photosynthesis).

Subsurface microbial biota is a recent discovery. Thus, bacterial life has now been found hundreds of meters underground in shales, limestone, and other rocks, and groundwater ages and other evidence indicate that there has been no contact with the surface for at least 10^4 and up to 10^6 years. The microbial activity seems not only to be hydrogen based (methanogenesis, acetogenesis, and sulfate reduction), but organotrophs also occur. Oil reservoirs in deep sediments have also been shown to harbor biota of hydrocarbon-degrading thermophilic sulfate reducers (Fenchel *et al.*, 1998).

Symbiotic Bacteria

There are numerous examples of bacteria living in or on other organisms; in many cases the adaptive significance of these associations is still not understood. Some cases of symbiosis between prokaryotes and eukaryotes, however, have been studied in detail; they are of scientific interest and sometimes even attract substantial economic interests.

Symbiotic polymer degradation is one such example. With few exceptions, animals are not capable of hydrolyzing and

utilizing structural plant polymers directly. Animals do not produce the necessary enzymes (cellulase, xylanase, etc.). Moreover, plant tissue generally contains insufficient amounts of N and P to sustain growth, and various secondary plant compounds are toxic to animals. Some herbivores therefore eat copious amounts of plant tissue with low digestion efficiency. They are typically confined to a few (taxonomically related) food plants because each grazer has only developed detoxification mechanisms against specific plant toxins; this applies to many insects. Many animals, however, have solved the problems of herbivory by maintaining consortia of anaerobic microbes in their gut system. Such systems have evolved independently in several groups of mammals and in a few groups of birds (ostriches, ptarmigans, and hoatzins), reptiles, and fish; they are also found in termites and cockroaches, in some sea urchins, and in shipworms.

The best known example is the rumen of cows and sheep. Ruminants exemplify pregastric fermentation. The rumen, which constitutes 10–15% of the volume of the animal, is anatomically a part of the esophagus. Its anaerobic content is a mixture of rumen fluid, ingested plant fragments, and microbes (approximately 10^{11} bacteria and 10^6 protists ml^{-1}). Ruminant saliva does not contain hydrolytic enzymes, but it is strongly buffered. Urea (the principal nitrogenous excretion product of mammals) is also excreted into the saliva, supplying the microbial community with N; it is a mechanism for preserving this essential element for the ruminant through internal recycling. Within the rumen a consortium of different bacteria and some eukaryotic microbes ferment carbohydrates (including cellulose and xylan) principally into acetate, butyrate, propionate, and $CO_2 + H_2$. The fatty acids are absorbed in the intestinal tract, and they constitute the energy and carbon source of the ruminant. Protein is exclusively provided by the digestion of microbial cells in the true stomach; thus, a cow does not profit from eating proteins because these are microbially hydrolyzed, deaminated, and fermented in the rumen prior to the stomach. In the rumen, methanogens convert H_2 into CH_4 ; the methane represents a (necessary) loss to the cow (approximately 15% of the food intake) and it rids itself of the gas through belching. Ruminants are thus totally dependent on their microbial symbionts; ruminants that have artificially been deprived of their rumen biota cannot survive on a normal diet. In addition to ruminants, pregastric fermentation is found, for example, in kangaroos, sloths, and colubine monkeys (Fenchel *et al.*, 1998).

Postgastric fermentation is more widespread (e.g., horses, rhinos, elephants, lemurs, koalas, lagomorphs, and several others; even humans probably profit slightly from their intestinal microbial biota in this way). Animals with postgastric fermentation possess one or more ceca containing a consortium of fermenting bacteria. Ingested food is first subject to acid digestion in the stomach, with subsequent absorption of monomers, whereas nondigestible plant polymers are eventually fermented in the cecum. In most termites and cockroaches, the principal cellulose decomposers (harbored in the hind gut) are protists (various types of specialized flagellates), although bacteria also play a substantial role in these microbiota.

Nitrogen fixation (the reduction of N_2 to NH_4^+) is a very energy-requiring, anaerobic process, which is known only from bacteria. It is widespread especially among free-living anaerobes

and microaerobes, and some aerobes have special adaptations to protect the nitrogenase complex from O_2 (e.g., some cyanobacteria and *Azotobacter*). Nevertheless, it is estimated that in terrestrial habitats more than 90% of N_2 fixation is symbiotic.

Symbiotic nitrogen fixation is of immense economic importance and since antiquity it has been known that legumes improve soil fertility. The great majority of plants belonging to the Leguminosae form root nodules that harbor the N_2 -fixing bacteria (*Rhizobium*). These bacteria normally live in soils; they especially thrive in the rhizosphere of legumes and often adhere to root hairs. Appropriate strains enter root hairs and induce the formation of root nodules. The bacteria transform into nondividing "bacteroids" that fix N_2 on the basis of carbohydrates provided by the plant. A hemoglobin (leghemoglobin) secures a sufficiently low O_2 tension while simultaneously allowing for aerobic metabolism, and the plant assimilates the formed ammonia.

Another type of symbiotic N_2 fixation is found in several unrelated species of trees (e.g., *Alnus*, *Myrica*, and *Hippophae*); it is due to the bacterium *Frankia* (an actinobacterium), which also forms root nodules. The adaptive significance of different examples of symbiotic cyanobacteria in plants seems also to be that of N_2 fixation (e.g., in cycads). The water fern *Azolla* harbors N_2 -fixing *Anabaena*; the fern plays a role as green manure in rice cultivation.

There are many other interesting examples of symbiotic relations between bacteria and eukaryotes, including relatively exotic cases such as symbiotic bacteria that confer bioluminescence on certain species of fish and squids. Special mention should be made of various marine invertebrates that farm chemoautotrophic bacteria (especially sulfide oxidizers and, in a few cases, methane oxidizers). First thoroughly studied in the deep-sea hydrothermal vent fauna, the phenomenon has subsequently been found to be widespread in shallow waters as well. Pogonophorans (and the related vestimentiferans) and some bivalves and oligochaetes are gutless and entirely dependent on their symbionts for food; the hosts in turn provide the bacteria with necessary oxygen and sulfide via their circulatory system. Other bivalves maintain sulfur bacteria in their gills, but they are simultaneously capable of filter feeding. Some anaerobic protozoa maintain symbiotic methanogenic or sulfate-reducing bacteria. The protozoa (mainly certain ciliates) have a fermentative metabolism with H_2 production; the symbionts in turn are H_2 scavengers, thus maintaining a low intracellular H_2 tension which again enhances the energy efficiency of the host metabolism.

Unicellular Eukaryotes (Protists)

Protists are known to include many unrelated eukaryotic groups. Eukaryote cells differ from prokaryotes in possessing a cytoskeleton and membrane-covered organelles, among which mitochondria and chloroplasts are recognized as being descendants of endosymbiotic aerobic bacteria belonging to the α group of proteobacteria and to cyanobacteria, respectively. Protists have a much greater size range than bacteria; the smallest free-living species measure approximately 3 μm and the largest may attain sizes of several centimeters.

Phagocytosis is probably a primary property of eukaryotic cells and most extant species depend on particulate food (mainly bacteria or other protists). Many groups have acquired chloroplasts; this has apparently happened independently in different taxa and examples of "chloroplasts," which represent intermediate stages between an endosymbiont, and an organelle are known. Many species have secondarily lost chloroplasts and thus the ability of photosynthesis. Within many groups of phototrophs the ability of phagocytosis has been retained (mixotrophs, found for example among chrysomonads and dinoflagellates); in other groups (e.g., diatoms and green algae) phagocytosis has been irreversibly lost. A few species (some ciliates and foraminiferans) are capable of retaining chloroplasts from their prey cells; the chloroplasts remain functional for some days and this is exploited by the "host." Many heterotrophic protists harbor endosymbiotic phototrophs. Very few protists subsist on dissolved organic matter; in most habitats they would be inferior competitors to bacteria simply due to their larger size. The majority of protists are aerobes; a few specialized protists, however, are obligate anaerobes depending on a fermentative metabolism. Tolerance to extreme conditions is limited relative to that of some bacteria, but otherwise protists are omnipresent; primarily they are the principal consumers of bacteria in all types of environments and phototroph protists are largely responsible for primary production in aquatic habitats. (Fenchel, 1987)

Phototrophs

Macrophytes (macroalgae and vascular plants) are responsible for much of the primary production along shallow coastal waters and lakes. In offshore waters and in the oceans, unicellular phototrophs are solely responsible for light-driven CO_2 reduction and they thus largely constitute the basis for aquatic life. Characteristic annual succession patterns (with respect to species composition) occur in temperate seas and lakes. During winter, mineral nutrients are brought to the photic zone from deeper waters. In early spring, when light conditions allow, a bloom of diatoms develops; the bloom is brought to an end by zooplankton grazing and by nutrient limitation. During summer, phytoplankton is dominated by small forms (chrysomonads and prymnesids), which perform better at low nutrient concentrations; autumn is often characterized by a bloom of large dinoflagellates. In tropical waters which are thermally stratified throughout the year, competition for mineral nutrients is intense and small species prevail. Upwelling areas, such as off the coast of South America, support production of large phytoplankton species and thus represent an exception to this generalization.

Phytoplankton biomass is primarily limited by mineral nutrients – in most marine areas by inorganic N, although P limitation is also known and may be the rule in limnic systems. Diatoms may be limited by available Si and it has been inferred that Fe limits primary production in the Southern Ocean. Increased nutrient additions, especially from fertilizers, via river runoff and groundwater seepage have caused increased phytoplankton production and biomass in offshore waters, bays, and estuaries in addition to lakes in many parts of the world. Such eutrophication may be detrimental to

rooted vegetation (due to competition for light) and in some cases may result in widespread anoxia or hypoxia of bottom waters due to an increased input of organic material (Falkowski and Knoll, 2007).

Large phytoplankton cells are consumed by various zooplankters (copepods, etc.), which again serve as food for fish. Small phytoplankters are to a large extent consumed by protozoa, which then enter planktonic food chains. Many benthic filter feeders (e.g., mussels) also depend mainly on phytoplankton cells.

In shallow aquatic sediments phototrophic protists are important primary producers even though the photic zone extends only 2 or 3 mm beneath the sediment surface. In these biota, diatoms, euglenoids, and dinoflagellates are especially important (together with unicellular and filamentous cyanobacteria).

Phagotrophic Protists

Phagotrophic protists seem to be the principal consumers of bacteria in almost all habitats. In plankton, it is particularly the small (4–10 μm), heterotrophic flagellates that play a role as bacterial consumers, thus closing the microbial loop (Figure 3). They occur at densities of approximately 10^3 cells ml^{-1} in most natural waters. Other groups of protists, especially ciliates, mainly consume larger prey such as heterotrophic flagellates and small phytoplankters, whereas heterotrophic or mixotrophic dinoflagellates feed on prey, which often exceeds their own size. In oceanic plankton, the large acantharians, radiolaria, and the planktonic foraminiferan *Globigerina* are mainly phagotrophs feeding on large prey; most of them also harbor endosymbiotic phototrophs. The three (unrelated) groups all produce skeletons (made of strontium sulfate, silica, and calcium carbonate, respectively) and the sedimented skeletal remains of the two latter groups characterize many oceanic sediments.

Sediments, especially from shallow waters, harbor high densities of a wide variety of phagotrophic protozoa, including amoebae, flagellates, and ciliates, filling a variety of niches especially with respect to food requirements and oxygen tension. Foraminiferans are characteristic of marine sediments; their niches are in part taken over by testate amoebae and by heliozoans in lake sediments. Deeper marine sediments harbor large foraminifera and in deep-sea sediments the peculiar xenophyophoreans grow to a size of several centimeters and possess a skeleton made of barite.

In soils, small ameboid protozoa are most important as bacterial consumers; testate amoebae, heterotrophic flagellates, and ciliates are also present. Soil protozoa have various adaptations to thin water films (small size) and desiccation (formation of desiccation resistant cysts and life cycles, which allow exploitation of short periods with high moisture) (Fenchel, 1987).

Symbiotic Protists in Animals

Like prokaryotes, many protists occur as symbionts in animals; probably all animal species (including humans) harbor several protozoan symbionts. Symbiotic polymer degradation by flagellates in termites has already been mentioned. The most important type of symbiosis involving protists is that

between animals and intracellular phototrophs. Many aquatic invertebrates harbor such symbionts. In fresh waters the symbionts are usually the green alga *Chlorella* (e.g., in freshwater sponges, the coelenterate *Chlorohydra*, and in the ciliate *Paramecium bursaria*). Most marine cases are based on dinoflagellates (*Symbiodinium*), but other groups (e.g., diatoms, chlamydomonads, and prymnesids) are also represented. In most cases the host combines the nutrition derived from the symbiont (usually in the form of carbohydrates) with particulate food; in some cases, it has been shown that the hosts can subsist entirely on the basis of the symbionts, and in a few cases the ability of phagotrophy has been lost. The most important marine example is that of phototrophic symbionts in reef-building corals; the symbionts are not only responsible for a significant share of primary production of coral reefs but also facilitate carbonate deposition of the host during active photosynthesis. A similar situation applies to giant tropical shallow-water foraminiferans; like corals, they are responsible for the formation of limestone deposits (the Cheops Pyramid is built from limestone consisting of the calcareous remains of the Eocene foraminiferan *Nummulites*). Other marine invertebrates harboring phototrophic symbionts include the giant clam *Tridacna* and various coelenterates (Fenchel, 1987).

Roles of Microbes over Geological Time and in the Contemporary Biosphere

This section briefly explores the role of microbes in the evolution of biogeochemical element cycling on a global scale. The Earth (and the solar system) arose approximately 4.6×10^9 years ago; the earliest sign of life dates to approximately 3.8×10^9 years ago (mid-Archean) in the form of a graphite particle found in sediment on the west coast of Greenland. Their contents of stable C-isotopes indicate that they derive from organic matter that was synthesized via the Calvin cycle presumably by some sort of bacteria. It is generally accepted that life arose on Earth, perhaps 4×10^9 years ago, under anoxic (and presumably chemically reducing) conditions, and that the atmosphere eventually became oxic as a result of oxygenic (cyanobacterial) photosynthesis. There is convincing evidence that atmospheric O_2 slowly increased from very low levels during the Precambrian. The earliest evidence of cyanobacteria (from Warrawoona in Australia and the Fig Tree Formation from southern Africa) is in the form of stromatolites, which are fossil remains of microbial mats. The nature of the oldest of these, approximately 3.5×10^9 years old, however, has been contested. Somewhat younger Stromatolites – remains of cyanobacterial mats sometimes with well-preserved fossil bacteria that were very similar to present-day cyanobacteria – are known from throughout the remaining Precambrian. Evidence of an increasing O_2 tension of the atmosphere derives from banded iron formations: laminated (> 3 to 2×10^9 years old) deposits containing partly oxidized Fe. The general interpretation is that as O_2 (resulting from photosynthesis) appeared in the atmosphere, dissolved reduced iron, in the otherwise anoxic oceans, was oxidized at the sea surface to become insoluble oxidized Fe that again gave rise to the deposits. Atmospheric O_2 levels thus initially remained low due to oxidation of reduced minerals on the surface of the

Figure 4 The global N cycle (simplified). Crucial processes (biological N_2 fixation, nitrification, and dissimilatory denitrification) are exclusively bacterial. Denitrification and nitrification also imply production of N_2O and other oxidation levels of N.

Earth (and presumably due to the early origin of biological O_2 respiration). Later, the O_2 level increased, reflecting the accumulation of fossil organic material in sedimentary rocks. There is evidence that the O_2 level had increased to $>1\%$ of the current atmospheric level approximately 2×10^9 years ago (early Proterozoic). When metazoa arose 600 to 700 My ago, atmospheric O_2 must have reached at least 10% of the current level (according to requirements of extant invertebrates), but it could also have been higher.

The conclusion is that oxygenic phototrophs, quite similar to modern cyanobacteria, must have evolved at least 3×10^9 years ago. It seems likely that all basic types of bacterial metabolism had also evolved by then, although this is speculative.

The time for the origin of eukaryotic cells is unknown, although molecular data (Figure 1) suggests “deep roots,” there is (molecular) evidence suggesting that mitochondria (and thus “modern” eukaryotic microbes) arose approximately 2×10^9 years ago (or slightly earlier than fossils that have been interpreted as remains of protists). In all circumstances, when metazoans and the first macroalgae arose 600 to 700 My ago, almost all major biochemistry and metabolic pathways had evolved in microorganisms and with them the basic biogeochemical cycles as are known today. Colonization of land approximately 100 My later and the evolution of vascular plants and fungi, however, must have had a profound effect on the biosphere and on mineral cycling (Schopf and Klein, 1992).

There is not enough space here to describe the major biogeochemical element cycles (notably the C, N, and S cycles) in detail. A view of the nitrogen cycle (Figure 4), however, further illustrates the immense importance of microbes in the biosphere. Atmospheric N_2 is fixed by bacteria, but reactive N is also added to the biota as N oxides formed during electric discharges in the atmosphere and by industrial N_2 fixation. In cells, N occurs in a reduced form in organic matter and it is released as NH_4^+ when organic matter becomes mineralized. Through nitrification (a bacterial process) it is oxidized to NO_3^- which can be utilized (through assimilative reduction)

by plants. The only pathway back to N_2 , however, is denitrification, an anaerobic bacterial process that is necessary for the completion of the global N cycle and ultimately regulates the amount of reactive N available to the biota.

The important mechanisms that control particular microbial processes are largely understood. However, the complexities of the cycles and the many positive and negative feedbacks render it difficult, or perhaps impossible, to make predictions of the effect of environmental changes on an ecosystem or on a global scale. An example is atmospheric CH_4 , which is a greenhouse gas. The basic sinks (abiotic atmospheric oxidation and microbial oxidation in soils and other biota) and sources (mainly microbial methanogenesis primarily in wetlands including rice paddies, in lakes and in the sea, and in ruminants and termites; to a lesser extent through biomass burning and natural gas production) have been identified. It is also known that atmospheric levels (currently approximately 1.8 ppm) have increased (by approximately $1\% \text{ year}^{-1}$) during the past century. However, the effect on CH_4 levels as a function of climate change is in practice impossible to predict. Both CH_4 production and oxidation increase with temperature, and melting of tundras will enhance methanogenesis, but other temperature-correlated factors may affect both processes either way. Determinants of methanogenesis also include input of organic C, competitive interactions with denitrifiers, and sulfate- and iron-reducing bacteria; anthropogenic factors such as the extent of rice paddies and ruminant husbandry should also be included (Falkowski *et al.*, 2008).

Microbes and Man

There are many relationships between humans and microbes and they affect us on many levels of our existence. We are hosts to many prokaryotic and eukaryotic symbionts in addition to being victims of bacterial and protozoan pathogens. Humans have also – long before the existence of microbes was

recognized – utilized microbial processes and learned to prevent some adverse effects of microbial activities.

Thus, microbiological technologies which have been in use since prehistoric times include a variety of fermented foods involving lactic acid bacteria, propionic acid fermenters, and the production of vinegar from ethanol. In addition to their gastronomic qualifications, these techniques have served to prevent or control undesirable or even dangerous microbial spoilage of food, which is also the purpose of salting, smoking, or acidifying food. It has also been suggested that the use of spices and drinking of wine, rather than water, also served to control pathogenic microbes.

A quite different use of microbes is acid mine leaching, which was also in use long before the underlying mechanism was understood. Circulating water through crushed copper ore leads to acid conditions and dissolution of the ore; metallic Cu can then subsequently be recovered from the leachate by chemical methods. The underlying mechanism is that a consortium of acidophilic, chemoautotrophic bacteria (including *Thiobacillus ferrooxidans*) oxidizes both the reduced S and the reduced Fe of pyrite (FeS_2), which is omnipresent in many ores. The resulting sulfuric acid in turn dissolves the ore.

Biological sewage treatment serves primarily to mineralize organic material. Various types of sewage treatment are in use, depending, among other factors, on the scale of the plant; most systems involve aerobic and anaerobic microbial processes. An important aspect is the flocculation of bacteria, a process which is enhanced by the presence of protozoa. Removal of nitrate by microbial denitrification is another important function of biological sewage treatment, whereas phosphate is primarily removed by chemical precipitation. Mainly in smaller plants, anaerobic mineralization can be exploited to produce methane, which can be collected and subsequently used for heating.

In recent times, mass production of certain species of bacteria for the production of enzymes and antibiotics has played an important industrial role. Recently, genetically engineered bacteria or yeasts that express human protein genes (e.g., insulin and other hormones) have been used in the pharmaceutical industry.

Microbial diseases, of which there are many, represent the most direct encounter between humans and microbes. Through recorded history such diseases have played an important role for human populations, most dramatically illustrated, perhaps, by the recurrent plague epidemics in Europe from medieval times

to approximately 1700; however, many other bacterial diseases, such as cholera, tuberculosis, leprosy, and typhoid fever, and protozoal diseases such as malaria were also important. In North America, Europe, and in some other parts of the world serious bacterial and protozoan diseases have, especially after World War II, largely been brought under control due to the combined effects of hygienic measures, vector control (mosquitoes and rats), immunization programs, and antibiotics and other forms of chemotherapy. However, globally, tuberculosis and malaria remain among the most frequent causes of death. Many bacterial and protozoal diseases of livestock also remain economically significant. Evolving resistance to antibiotics and other types of chemotherapy in agents of disease in humans and animals may represent an increasing problem and indicate that our interactions with pathogenic microorganisms are not a closed chapter in human history.

Glossary

Bacterial mutualist A bacterium that interacts closely with a host and significantly enhances the host's fitness.

Bacterial parasite A microbe that interacts closely with a host and significantly reduces the host's fitness.

Endosymbiotic bacteria Bacterial species that live within the cells of hosts, are transmitted by hosts to their offspring, and often cannot survive outside of the host.

Infection Colonization of a host organism by bacteria that reproduce within the host and are ultimately transmitted to new hosts.

Introduction

The primitive earth was dominated by single-celled bacteria and archaea; the two major lineages of unicellular organisms that lack nuclei and the membrane-bound organelles of the eukaryotes. Beginning with the first fossil evidence of life, approximately 3.5 billion years ago and continuing for 2 billion years thereafter, most evidence of life appeared bacterial and archaeal. Not until a period that began about 1.5 billion years ago did eukaryotic lineages emerge and only in the last 1 billion years did multicellular plants and animals begin to diversify and ultimately to dominate. Thus, we can imagine a period of at least 2 billion years in which bacteria and archaea persisted mostly as free-living cells in the terrestrial and aquatic habitats. The last 500 million years of earth's history has witnessed an explosion in eukaryotic diversity including major radiation events of animal and plant lineages. This diversification of eukaryotic lineages has also driven a massive and parallel radiation of symbiotic bacteria (Sachs *et al.*, 2011b). Although archaea can also form symbioses with eukaryotic hosts, these interactions do not appear as common or diverse.

In the last billion years bacterial lineages have evolved a diverse array of mechanisms to gain entry into the tissues and cells of eukaryotes and to proliferate within these hosts (Medina and Sachs, 2010; Toft and Andersson, 2010). Here, the author refers to both harmful and beneficial bacterial infections as symbioses, a term used to describe any persistent and intimate association between microbes (the symbionts) and host species (animals, plants, or other eukaryotes; Medina and Sachs, 2010). Much of the research uncovering the mechanisms of symbiotic infection has focused on microbial parasitism (Sachs *et al.*, 2011a). In parasitic interactions, the microbes infect and actively exploit hosts resulting in reduced host survival and reproduction (evolutionary fitness). Bacterial parasites are a major challenge to human health and also represent a huge cost in terms of lost crops and animal stocks. However beneficial bacterial infections are known to be just as ubiquitous as parasites and can be found in virtually any eukaryotic species and in any ecosystem (Sachs *et al.*, 2011b). Such mutualistic infections occur when microbes infect and offer resources and services to hosts that enhance host fitness. Here the author's goal is to trace the deep evolutionary history of bacterial symbiosis and particularly to examine events leading to the origins and macroevolution of the bacterial mutualism.

Bacterial mutualists exhibit a great deal of lifestyle variation in their interactions with the eukaryotic hosts. Three key sources of variation are thought to bear particular importance to the evolution of mutualist bacterial lineages (Sachs *et al.*, 2011b). One source of variation is the degree to which the bacteria reproduce inside their host versus free in the environment. Many (and perhaps most) mutualist bacteria infect hosts but also spend a large portion of their lifecycle free in soils or aquatic environments (Sachs *et al.*, 2011a). The animal and plant hosts of these bacteria are born symbiont-free and thus must acquire their infections from the environmental pools (Szathmari and Maynard-Smith, 1995; Nyholm and Mcfall-Ngai, 2004; Sachs *et al.*, 2011a). At the opposite end of the spectrum are endosymbiotic bacteria and bacterially-derived organelles (Sagan, 1967; Keeling, 2010), which are the bacteria that cannot live independently without the hosts, only divide within host tissue and can only form new infections via transmission from host parent to offspring. A second source of variation is the array of animal and plant host tissues that bacterial mutualists can inhabit, including cell surfaces ranging from skin, mucosa, leaves and roots, and spaces between and within cells. In some cases the hosts have evolved specialized structures to house beneficial symbionts (e.g., Douglas, 1989; Bright and Sorgo, 2003; Nyholm and Mcfall-Ngai, 2004; Currie *et al.*, 2006; Goettler *et al.*, 2007; Vaishnavi *et al.*, 2008) whereas in other cases beneficial bacterial symbionts can range widely within unstructured host tissues (Hirose *et al.*, 2009; Kaltenpoth *et al.*, 2009; Sachs *et al.*, 2011b). A final source of variation is represented by the array of mechanisms by which bacterial mutualists can provide fitness benefits to hosts, including the transfer of key nutrients, protection via toxicity as well as bioluminescence (Sachs *et al.*, 2011a, b). As described below each of these variables can have implications for the long-term evolution of symbiotic bacterial lineages.

The author describes how the study can be done on the diversification of such mutualist bacterial traits over the millions of years that they have developed and moreover how the study can be done on the origins of bacterial mutualist lineages and their persistence over evolutionary time. One approach to characterize such evolutionary history is to distill the key events and investigate the forces that shaped them (Szathmari and Smith, 1995). Bacteria can be understood to have undergone several major transitions in their evolutionary history and route to become mutualists with the eukaryotic

hosts. Some of these transitions represent key evolutionary milestones that have occurred many times in the history of bacteria. Five of these evolutionary transitions will be explored in depth over the course of this article (Sachs *et al.*, 2011b).

Evolutionary Origins of Bacterial Associations with Hosts

In the past history of bacteria, evolutionary origins of host association have occurred when environmentally existing bacteria initially evolved to form persistent and intimate interactions with the eukaryotic hosts (Sachs *et al.*, 2011b). Since the planet was first dominated only by the bacterial and archaeal cells, none of these organisms had large bodied hosts to live in or infect. Once eukaryotic lineages evolved, in particular the diversification of animals and plants, there were many evolutionary origins in which bacteria that once lived independently in the environment evolved to form intimate and persistent associations with these hosts (Sachs *et al.*, 2011b). For bacteria to undergo the transition to host association they must have had to overcome major hurdles, including evasion of host defenses, competition with other microbes to inhabit host surfaces, uptake of novel compounds in hosts and the ability to gain transmission from one host to the next (Sachs *et al.*, 2011b). To examine the difficulty of these potential hurdles, evolutionary methods can be used to assess the degree to which origins of host association are rare in bacterial lineages (Sachs *et al.*, 2011b).

One method to quantitatively investigate past evolutionary events is to build an evolutionary tree of genetically related species (a phylogeny) and then use the tree as a tool to test evolutionary hypotheses. The first step in this case is to reconstruct a species phylogeny of bacteria. This is becoming increasingly easier with the great availability of whole genome sequences (e.g., Wu *et al.*, 2009). The recent analysis by Wu and colleagues (2009) used genetic data from fully sequenced bacterial genomes to reconstruct an evolutionary tree of over 350 bacterial species. Because of the large amount of data that is available from the whole genome sequence, a very robust phylogeny can result (Wu *et al.*, 2009; Sachs *et al.*, 2011b; see Figure 1). The next step is to map species traits that can be added to the tree to study past events. In this case the traits of importance characterize each bacterial species in terms of their interactions with eukaryotic hosts (Boussau *et al.*, 2004; Merhej *et al.*, 2009; Toft and Andersson, 2010; Philippot *et al.*, 2010). Many bacterial species in this analysis exhibit no symbiotic interactions and are thus characterized as environmental whereas other species interact intimately with eukaryotic hosts and are categorized as parasites and mutualists depending on their fitness effects on hosts during infection (Sachs *et al.*, 2011b). Once a phylogenetic tree has been reconstructed for a lineage and phenotypes (traits) became known for each of the species, algorithms can be used to infer ancestral character states onto the tree. Such inference methods (known as ancestral state reconstruction) can be used to retrace the order of evolutionary events as well as the number of times the particular traits have independently evolved within a lineage.

Analyzing the evolution of host association origins across bacteria (Wu *et al.*, 2009; Toft and Andersson, 2010) a couple of

conclusions can be made. First of all, simply from viewing the tree (Figure 1) it becomes clear that many independent origins of bacterial symbiosis have evolved. These origins can be found in almost every well-known lineage. For instance, on the 350 species tree a minimum of 42 origins of host-association are inferred from the environmental (free living) ancestral condition (Sachs *et al.*, 2011b). This pattern is interesting because it suggests that the hurdle in evolving from an environmental bacterium into a symbiont might not be as difficult as first imagined. Secondly, it appears that these origins of host association are more-or-less randomly distributed among bacteria (Sachs *et al.*, 2011b). Whereas some well-studied lineages appear to have many origins (Proteobacteria, Actinobacteria, and Firmicutes; Figure 1) and a few lineages (such as Chlorobi, Chloroflexi, and Planctomycetes) have never evolved the host association (Madigan *et al.*, 2009; Wu *et al.*, 2009; Toft and Andersson, 2010) there does not seem to be any significant bias where the origins occur on the tree (Sachs *et al.*, 2011).

To explore the mechanisms of symbiosis origins, researchers have begun to investigate the changes within the bacterial genomes that are correlated with these evolutionary transitions. One newly available approach is to study bacteria for which whole genome datasets are published and to compare the genomes of bacteria with different lifestyles. The goal here is to specifically retrace the particular sets of genes or genetic loci that are gained or lost concurrently with the origins of host association. Two interesting results have come from these studies so far. One pattern is that there are often few consistent genetic differences between host associated and environmental bacterial species (Carvalho *et al.*, 2010). Similarly, few genetic differences are often found between related bacteria that are beneficial versus those that are harmful to the hosts during infection (Sachs *et al.*, 2011a). Among the small set of genes that do differ in host associated and environmental species, many of them exhibit a strong evidence of horizontal gene transfer (movement of genes from one organism to an unrelated organism; Dale *et al.*, 2001; Horn *et al.*, 2004; Frank *et al.*, 2005; Ruby *et al.*, 2005; Ma *et al.*, 2006). Whereas only a few studies have rigorously compared the genetics of environmental versus beneficial or harmful host-associated bacteria (Dale *et al.*, 2001; Horn *et al.*, 2004; Frank *et al.*, 2005; Ruby *et al.*, 2005; Ma *et al.*, 2006; Carvalho *et al.*, 2010), one initial conclusion that can be made from these studies is that horizontal gene transfer is likely an important mechanism that promotes shifts in the lifestyles of bacteria. This pattern suggests that transitions to host association might be caused by a relatively smaller set of genes that are mobilizable among the bacterial lineages. At a broader level, these data suggest that very simple ecological factors might consistently promote or constrain a bacterium to gain the ability to infect eukaryotic hosts. These ecological factors might be as simple as access to habitats with compatible hosts and access to compatible genes (gained from other bacterial lineages) that allow an environmental bacterium to infect the hosts (Sachs *et al.*, 2011b).

The Origins of Bacterial Mutualism

Among the host-associated lineages, bacterial mutualists are incredibly diverse. Beneficial bacteria are diverse in the sense

Figure 1 Inferred evolutionary history of bacterial host-association. Ancestral states of symbiosis are inferred on a bacterial evolutionary tree (modified from a previously published figure; Sachs JL, Skophammer RG, and Regus JU (2011b) Evolutionary transitions in bacterial symbiosis. *Proceedings of the National Academy of Sciences USA* 108:10800–10807). The tree is reconstructed from 31 single copy genes taken from 350 bacterial species for which whole genome data are available (Wu *et al.*, 2009). Phyla and proteobacterial classes are labeled with their full names (e.g. Gammaproteobacteria; Firmicutes) or single-letter abbreviations (a=Acidobacteria; d=Deferribacteres; q=Aquificae; e=Elusimicrobia; v=Verrucomicrobia; p=Planctomycetes). Branch colors represent host-associated traits on the tips of the tree and inferred states on ancestral nodes (black=environmental; blue=commensal; green=mutualist; red=parasite). Host association traits were obtained from a prior review (Toft and Andersson, 2010). Sachs and colleagues (2011b) inferred a minimum of 42 origins of host-association (labeled 1–42).

that this strategy has not only evolved independently in many anciently diverged lineages but also because so many types of hosts are infected in many different ways (Sachs *et al.*, 2011a). Other questions risen by the author include: what evolutionary process brought about these interactions in the first place? In other words, from the perspective of the bacterial evolutionary tree, what are the ancestral conditions that predate the origins of bacterial mutualists? Furthermore can evolutionary predictions be made about scenarios

that favor the evolution of bacterial mutualists from other lifestyles?

Most of these questions remain unresolved. However, just as the author has done above for the origins of host association, information from bacterial phylogenies can be used to begin retracing the origins of bacterial mutualism. Perhaps the most perplexing question about bacterial mutualists is where they came from (Ewald, 1987; Szathmary and Smith, 1995; Corsaro *et al.*, 1999; Moran and Wernegreen, 2000; Medina and Sachs,

2010). Two competing hypotheses describe evolutionary scenarios for the origins of bacterial mutualism. One hypothesis proposes that bacterial mutualists have come about from parasitic ancestors that have evolved to be less harmful over time to the point that beneficial interactions could evolve with the hosts (Ewald, 1987). This attenuation of virulence is thought to be linked with the type of transmission that the bacteria exhibit (Ewald, 1987). Many bacteria are horizontally transmitted, meaning that individual bacteria travel from one host to a new and unrelated host to initiate a new infection. Horizontal transmission can actually promote parasitism of hosts because the ability to escape and infect a new host allows the bacterium to exploit the current host without harming itself (Fine, 1975). In contrast, vertical transmission occurs when bacteria are transmitted from a host to its offspring and in this case the bacteria can benefit themselves by being mutualistic (Fine, 1975). In a seminal paper Paul Ewald hypothesized that microbial mutualism can evolve from parasitism when there are evolutionary shifts from horizontal to vertical transmission among the hosts (Ewald, 1987). The author reviews data for and against this hypothesis below. The competing hypothesis states that bacterial mutualists must evolve directly from ancestors that lived free in the environment (Ewald, 1987). This hypothesis is based on the idea that it is difficult or impossible for bacteria switching from parasitism to mutualism because of constraints of genetic architecture (Moran and Wernegreen, 2000).

To examine empirical support for these scenarios we can again use the evolutionary reconstruction of bacterial species to infer past evolutionary transitions. However, this kind of analysis (that investigates transitions between different bacterial lifestyles) must be used with caution. The goal of hypothesis testing here is to examine general patterns of evolutionary transitions, however the dataset that is being used is relatively small because there are very few bacterial species on the tree (350 compared to the likely millions of actual bacterial species on earth), and because only a fraction of them ever associate with hosts. This sparse sampling means that many transitions are missing and that some inferred transitions might be spurious because intermediate steps have not been sampled. With these caveats in mind it can be seen in the dataset that both the above hypotheses are supported. Three independent transitions from parasitism to mutualism can be observed on the tree and also mutualist lineages are inferred to have originated directly from the environmental ancestors (Figure 1). Unfortunately, there is not enough data on the tree to sufficiently test Ewald's hypothesis (1987) that the evolution of vertical transmission is responsible for the transitions from parasitism to mutualism. Phylogenies that examine specific bacterial lineages that include different host-associated lifestyles have also been used to examine and test these hypotheses and are consistent with the conclusion that mutualist bacteria can evolve from both environmental and parasitic ancestors (Sachs *et al.*, 2011b).

The Evolutionary Maintenance of Bacterial Mutualism

Mutualism is inherently unstable over evolutionary time (Sachs and Simms, 2006). For any cooperative interaction among species to be maintained, a mechanism must be in

place to prevent the invasion of individuals that gain benefits from the interaction but do not pay any costs (cheaters). Since cheaters only take but do not give in an interaction they can be strongly favored by natural selection. The challenge then, is to explain how natural selection can promote cooperative individuals in a mutualism over cheaters. Three types of models for the maintenance of mutualism have been proposed (Axelrod and Hamilton, 1981; Bull and Rice, 1991; Sachs *et al.*, 2004; Foster and Wenseleers, 2006). The simplest of these models is called byproduct cooperation, which occurs when the bacterial partner cooperates with hosts as an automatic consequence of an unrelated and selfish trait (Sachs *et al.*, 2004). For instance, many bacteria produce toxins and antibiotics to protect themselves in the environment and these bacterial traits can automatically offer protection to hosts. One interesting outcome of such 'selfish cooperation' is that there is no opportunity for the bacterium to cheat since the cooperative trait usually bears no net cost of the bacterium. The next type of model, called partner fidelity feedback, works under the idea that there is a feedback in benefits between the bacterial and host partners. Feedbacks can work whenever the host and symbiont interact repeatedly or over a long enough period that their fitness interests become linked. The best example of this linkage has already been described in the example of vertical transmission. When hosts transmit bacteria from parent to offspring, both the bacterium and host can share a common interest in maximizing each other's survival and reproduction. The last type of model, called partner choice, occurs when the host can exert some level of control over the bacteria and has the ability to act as a selective force in the bacterial population. Specifically, with partner's choice the host can selectively favor cooperative over uncooperative infections and thus select for mutualists (and select against cheater mutants). To some degree, each of these models was developed without any particular biological interaction in mind and none of these models was initially created to study microbial symbioses. Hence, an interesting question to address is the degree to which different bacterial-host mutualisms are stabilized by byproducts, partner fidelity, or partner choice (Sachs *et al.*, 2011b).

Byproducts cooperation has not had a great deal of attention from empirical biologists. In part, this might be because it can be difficult to resolve byproducts cooperation into clear mechanisms. Yet, a feature that differentiates byproducts from partner fidelity feedback and partner choice is that the cooperative act bears no net cost for the bacterium; the trait is beneficial to the bacterium for some purpose unrelated to the host and exists irrespective of the host interaction. As described above, bacteria that exhibit toxicity or antibiotics might fulfill this description well. For instance, bacteria in the lineage Actinomycetes produce antibiotics as a benefit for their ant hosts. In this case the ants are fungus farmers; they grow fungi from the leaf litter collected in the forest and then eat the fungus for sustenance. The farming ants use the Actinomycete bacteria that grow on their exoskeleton to keep their fungal gardens pathogen-free (Currie *et al.*, 1999). As described above the trait of antibiotic production is a function that also benefits bacteria directly when it is in the environment, and this trait is expressed whether the bacteria are in the host or

not (Currie *et al.*, 1999; Sachs *et al.*, 2011b). Another likely example comes from bacteria that inhabit the lower gastrointestinal tracts of humans, *Bacteroides thetaiotaomicron*. One of the benefits that these bacterial mutualists are thought to provide for humans is to breakdown macromolecules that we cannot otherwise digest because we lack the enzymes to do it (Sonnenburg *et al.*, 2005). This is likely true for many functions that occur within the human body as the bacteria that inhabit us and carry our beneficial functions within the human body contain about 100 times as many genes as are found in our genome. Specifically in the case of *B. thetaiotaomicron*, the action of breaking down complex energy-filled food molecules into simpler compounds also must benefit the bacteria directly (Sachs *et al.*, 2011b). As there has been so little research on this topic there are likely many more examples such as these, but more work needs to be done to understand the breadth and importance of the byproducts cooperation in bacterial mutualists.

Partner-fidelity between bacteria and their hosts occurs when the bacteria are vertically transmitted from hosts to their offspring (Fine, 1975) and more generally in any scenario in which the symbiont interacts intimately with the host for a prolonged period (Sachs *et al.*, 2004; Sachs and Wilcox, 2006). Whereas vertical transmission is only one mechanism to maintain partner fidelity between bacteria and hosts, it remains the only driver that is well characterized or understood. In most cases vertically transmitted bacteria are very cooperative with hosts, but some exceptions exist. Some vertically transmitted bacteria harmfully manipulate the host's reproduction to maximize their own spread in the host population. For instance, many vertically transmitted symbionts are only passed on through females to offspring (via the ovum) and thus male hosts represent an evolutionary dead-end to these symbionts. In the case of *Wolbachia*, a common bacterial symbiont of most insects, have sometimes evolved mechanisms to bias host sex ratio toward females in order to maximize their own transmission (Stouthamer *et al.*, 1999).

Partner choice occurs when hosts exhibit mechanisms to selectively benefit beneficial bacterial partners and or punish harmful strains (Sachs *et al.*, 2004). Yet, how can a large eukaryotic host such as a plant or animal individually recognize individual bacterial genotypes and species and react toward them differentially in an adaptive manner? Despite a great deal of research, this question remains one of the major unsolved mysteries of symbiosis. One recent idea of how hosts can manage a complex group of genetically diverse symbionts is that hosts spatially separate their symbionts so that each genotype can be dealt with on an individualized basis (Denison, 2000; Sachs *et al.*, 2004, 2011b; West *et al.*, 2002a, b). Consistent with this hypothesis, many hosts of beneficial bacteria have evolved specialized structures that only exist in the context of a bacterial interaction and that have the potential to order symbionts into a fine level of spatial structure (e.g., Douglas, 1989; Bright and Sogo, 2003; Nyholm and Mcfall-Ngai, 2004; Currie *et al.*, 2006; Goettler *et al.*, 2007; Vaishnav *et al.*, 2008). In many of these hosts, little is known about how or whether the structure promotes partner choice. Perhaps the best understood system is in legumes that are infected with root-nodule forming bacteria (rhizobia) that fix

nitrogen for the host in exchange for plant sugars (Sprent *et al.*, 1987). In this case each nodule is most often infected by a single rhizobial genotype and thus nodules serve as a structural means for the plant to reward or punish rhizobial strains depending on how cooperative they are (Kiers *et al.*, 2003; Simms *et al.*, 2006; Sachs *et al.*, 2011a). The question is whether other hosts can wield such power over their bacterial symbionts. Some animals that host gastrointestinal bacteria have evolved complex crypt structures within their guts that appear specially to compartmentalize bacterial symbionts. But whether these crypt structures actively enforce partner choice is poorly understood. Humans exhibit crypt structures in their gastrointestinal tracts that bear importance to interaction with gut flora (Vaishnav *et al.*, 2008) but it is not clear whether these crypts are necessary for the maintenance of the mutualism or not. In some lineages of stinkbugs, the hosts have bacterial symbionts in the genus *Burkholderia* (Kikuchi *et al.*, 2011) that proliferate in the specialized gut crypts. Interestingly, only the stinkbug species that exhibit these crypts form beneficial symbioses with *Burkholderia*. This pattern suggests that the structural separation of the symbionts is a prerequisite to the evolutionary maintenance of the interaction (Sachs *et al.*, 2011b), but more data are needed.

The Evolutionary Capture of Bacterial Symbionts within Host Lineages

Most beneficial bacteria exhibit a rich existence both inside and outside their hosts. Since symbiotic bacteria are often environmentally acquired by hosts, the bacteria experience long phases in which they persist in soils or water separated by infection and growth within the hosts. To maintain this dual lifestyle the host-associated bacteria must be able to replicate in diverse environmental settings and must also be able to successfully localize and infect new hosts (Bright and Bulgheresi, 2010). As discussed above in the paragraph on partner-fidelity feedback, a subset of bacteria have evolved the ability to be vertically transmitted within host lineages (parent to offspring) and thus have lost their independence. The evolution of strict vertical transmission allows the symbionts to completely lose any environmental phase and thus persist only within the tissues or cells of hosts. How does this process of symbiont capture evolve and is it driven by the hosts or bacteria themselves (Sachs *et al.*, 2011b)?

A conflict of interests over symbiont capture appears to exist. Whereas vertically transmitted symbionts appear to suffer reduced fitness over time, their hosts experience clear benefits (Frank, 1996; Sachs *et al.*, 2011b). A great deal of data has accumulated regarding the genomic consequences of evolving vertical transmission for bacteria. When bacteria make the transition from free-living to strict vertical transmission their population size drops as a consequence of losing environmental phases. This simple change is thought to have enormous consequences. One of the fundamental rules of population biology is that natural selection only works efficiently on large populations: once populations drop to a small enough size they are only effected by random genetic change and tend to evolve reduced fitness over time (Nilsson *et al.*, 2005). Consistent with this theory, vertically transmitted

bacteria are known to accumulate harmful mutations over time, lose genetic pathways (Moran, 2003; Toh *et al.*, 2006), and ultimately lose so much function that they are obliged to rely on the host for basic nutrient synthesis (Shigenobu *et al.*, 2000). Because of this evolutionary pattern of genome degradation, once vertical transmission evolves it can lead to an irreversible evolutionary endpoint for bacteria that ends in reliance on hosts (Sachs *et al.*, 2011b). Whereas all of these changes appear to be harmful for vertically transmitted symbionts, the hosts mostly experience benefits. Hosts that transmit their beneficial bacteria vertically guarantee that their offspring will also receive a beneficial infection and by virtue of partner fidelity promote selection for beneficial traits in their bacterial symbiont population (Sachs *et al.*, 2004; Sachs and Bull, 2005; Sachs, 2006).

Hosts appear to have evolved many types of structures and mechanisms that promote symbiont capture (Bright and Bulgheresi, 2010). In many cases hosts have specific structures that appear to have no purpose at all except to efficiently transfer bacteria to offspring (Sachs *et al.*, 2011b). It is fascinating to observe the diversity of specialized structures that animal hosts have evolved to engage in vertical transmission of bacteria (Bright and Bulgheresi, 2010). Moreover, animals have also evolved complex behaviors to pass on symbionts to offspring, for instance by smearing symbionts onto eggs, onto egg cases, into cocoons, or directly on growing offspring (Douglas, 1989; Kaltenpoth *et al.*, 2005; Hirose *et al.*, 2009; Kikuchi *et al.*, 2009; Kojima and Hirose, 2010; Kaltenpoth *et al.*, 2010). In contrast to these well-studied mechanisms, little is known about the ability of bacteria to promote or counteract symbiont capture. In some interesting cases bacteria can be seen to actively migrate within their host to get to the ovaries (Douglas, 1989) or even move outside the parent to infect offspring (Ran *et al.*, 2010). Nonetheless, these examples are not necessarily evident against hosts being responsible for symbiont capture. This is because once capture has evolved the bacteria have no other option to infect new hosts other than vertical transmission (Sachs *et al.*, 2011a). Whereas hosts clearly benefit from the structures and behaviors that promote symbiont capture, little is known about the evolution of capture from the symbiont's perspective.

Evolutionary Breakdown of Bacterial-eukaryotic Symbioses

A great deal of theoretical work has modeled the ecology and evolution of mutualistic interactions. Although bacterial mutualists are extremely common, much of this theory predicts that evolutionary instability which leads to the breakdown of mutualism over time (Sachs and Simms, 2006). One major prediction that has come from this work is that mutualisms are prone to shift into parasitism as cheater mutants invade mutualist populations (Axelrod and Hamilton, 1981; Bull and Rice, 1991). Another prediction is that mutualists can evolve to abandon their partners if costs of the interaction come to outweigh potential benefits (Keeler, 1985; Holland *et al.*, 2004). To what degree does evidence support these hypotheses of 'mutualisms-breakdown' (e.g., Sachs and Simms, 2006)? As described above, phylogenetic analyses can be used to retrace

the steps of evolution and infer how often mutualist bacterial lineages shift into other lifestyles. Interestingly, on the phylogenetic tree described above that samples lineages across bacteria (Wu *et al.*, 2009; Toft and Andersson, 2010; **Figure 1**) there are only two observed switches in which bacterial mutualists shift into other lifestyles. One of these shifts is a transition from a mutualist to a parasite and the other is a reversion back to an environmental (nonhost-associated) lifestyle (Sachs *et al.*, 2011b). Compared to the total number of lifestyle switches on the tree (72; Sachs *et al.*, 2011b) this dataset makes mutualism-breakdown seem surprisingly rare among bacterial lineages. Yet, it is difficult to tell whether this pattern represents an accurate reflection of bacterial evolution, or if it is an artifact of the dataset. As the author described above, the one big challenge to this kind of analysis is that so much of the dataset is missing: the tree represents a very sparse sampling of the actual bacterial diversity that exists.

For filling the potential gaps on the bacterial tree (Wu *et al.*, 2009; Toft and Andersson, 2010; **Figure 1**) one option is to 'zoom in' and investigate the potential for mutualism among much more closely related species or even strains of bacteria. Only in the last several years has there been a pulse of phylogenetic studies that have sampled bacterial lineages deeply enough to investigate the losses or gains of mutualism with hosts. Although several recent studies show repeated losses (abandonment) of bacterial mutualism (Nishiguchi and Nair, 2003; O'Brien *et al.*, 2005; Mueller *et al.*, 2010; Sachs *et al.*, 2010; Kikuchi *et al.*, 2011) no phylogenetic study that the author is aware of has uncovered a transition from mutualism to parasitism within a well-studied lineage. Hence, mutualism-breakdown appears to occur when bacterial mutualists evolve to abandon hosts (and revert to an environmental lifestyle) but there is extremely little evidence to support the idea that cheaters evolve within bacterial mutualist populations and drive transitions from mutualism to parasitism (Sachs *et al.*, 2011b).

Discussion

The history of bacterial interactions with animal, fungal, and plant hosts likely stretches back to the very origins of these lineages. It is virtually impossible to imagine organisms in any of these lineages existing without many intimate interactions with bacterial species (both harmful and beneficial). In the article the author has reviewed what is known about the evolution of bacterial interactions with eukaryotic hosts with a special focus on bacteria that cause beneficial infections (mutualists). Particularly, the author has explored the origins, maintenance, and ultimate breakdown of the bacterial interactions with hosts.

From the available data it can be concluded that the evolutionary milestone of bacteria first achieving symbioses with hosts has evolved many times in almost every bacterial lineage that is known to science. The repeated and convergent evolution of persistent and intimate interactions between bacteria and hosts suggests that these interactions are highly advantageous to bacteria, relatively easier to evolve and mostly independent of the specific habitat requirements (Sachs *et al.*, 2011b). Among the many intimate interactions that bacteria

exhibit with eukaryotes a large subset are beneficial to hosts. These bacterial mutualists have evolved from the diverse ancestors that include parasitic species (that evolved over time to offer benefits to hosts) as well as environmental bacteria (that evolved from unassociation with hosts directly to a beneficial interaction; Ewald, 1987; Sachs *et al.*, 2011b). Among these types of origins it appears that bacterial mutualism most often evolves directly from the ancestors that live free in the environment.

Bacteria that have evolved mutualist interactions with hosts are incredibly diverse and provide almost any kind of nutrient or biological service to hosts that can be imagined (Sachs *et al.*, 2011a). In some cases hosts have evolved mechanisms to actively select bacterial cooperation, for instance by selectively rewarding beneficial strains or by punishing cheaters (Sachs *et al.*, 2004). In other cases bacterial cooperation is maintained in a more passive manner because host and symbiont exhibit a feedback in terms of fitness benefits (Fine, 1975). Most bacteria that provide beneficial infections to hosts are acquired from environmental sources and exhibit horizontal transmission among hosts. In some cases, bacterial symbionts have switched to vertical transmission and thus can lose any environmental phase and evolve to live only within the hosts. Although transitions from horizontal to strict vertical transmission (symbiont capture) involve both host and symbiont evolution, both theory and evidence suggest that hosts are likely to dominate control of these transitions. Finally, the evolutionary breakdown of bacterial mutualism appears to be relatively rare compared to other transitions in bacterial symbiosis. This lack of transitions from mutualism to parasitism or other bacterial lifestyles suggests either that bacterial mutualisms are evolutionarily robust or that transitions from mutualism to other lifestyles are themselves unstable (and lead to extinctions or other stable states; Sachs and Simms, 2006).

Glossary

Autotrophy The ability of organisms to grow and reproduce independent of external sources of organic carbon compounds.

Eukaryote An organizational state of cellular organisms in which the genome of the cell is stored in chromosomes enclosed in a membrane-bound nucleus; all protists (algae and protozoa), fungi, plants, and animals are eukaryotes.

Euphotic The top layer of a water body through which sufficient light penetrates to support net photosynthesis. Rarely more than 100 m in depth, the euphotic layer can be as little as 1 m in turbid waters.

Heterotrophy The ability of organisms to grow and reproduce on organic carbon sources, taken in dissolved or particle form.

Metazoan Literally, a multicelled animal.

Mixotrophy The ability of a normally autotrophic organism to switch, circumstantially, to phagotrophy, or to support an otherwise meager food supply by resorting to the ingestion and assimilation of bacteria or their products.

Phagotrophy A type of heterotrophy that involves the consumption of protists, plants, or animals as food.

Photoautotrophy A type of autotrophy in which organisms gather light energy in order to reduce carbon dioxide to organic carbon; characteristic of green plants, most algae, and some prokaryotes.

Picophytoplankton The smallest (<2 µm) size class of photoautotrophic plankton.

Prokaryote Organizational state of cells lacking a membrane-bound nucleus and certain other organelles. Bacteria, including the cyanobacteria, are typically prokaryotic.

Introduction

“Plankton” is a collective term for organisms adapted specifically for a life in suspension in the open waters (the pelagic zone) of the sea and of such inland waters as lakes, reservoirs, and rivers. Planktonic organisms include protists (allegedly simple, unicellular, or colony-forming algal primary producers and their protozoan consumers), microorganisms, and certain types of small metazoan animals, all sharing a common liability to passive entrainment in water currents, generated by tide, wind, convection, gravity, and the rotation of the earth. The inherent physical variability of open-water habitats typically favors short life histories; rapid changes in dominant species composition, in response to fluctuating environmental conditions, contribute to the maintenance of high biological diversity in individual habitats and to the survival of a high species richness among planktonic assemblages in general. Genuinely, planktonic organisms – which include the plantlike chlorophyll-containing primary producers of the phytoplankton, the heterotrophic decomposer microorganisms of the bacterioplankton, and the more animal-like consumers of the zooplankton – are too small (often <20 mm) for their own intrinsic movements to be able to overcome, often or at all, the dispersive effects of water movement. Thus, “embedded” within the tireless and unconstrained motion of open water, planktonic organisms broadly go wherever the flow takes them. In this way, the ecology of plankton is inextricably related to the physical properties of the medium, the extent and limits of its motion, and the environmental conditions set within these bounds (Reynolds, 1997). This situation contrasts with that of most fish and other larger (>20 mm) animals of open

water – the “nekton” – whose swimming strength is usually able to overcome normal movement of the water.

The older literature promulgated a view that suspension in water was necessarily beneficial, supposing water to be something of an ideal habitat. Living in water does confer some notable positive advantages over terrestrial or aerial habitats. These include the mechanical (“Archimedean”) support water provides, as a consequence of its much greater density in comparison with air; its slow temperature fluctuations, as a consequence of its much higher specific heat than air; and its solvent properties, which maintain nutrients and metabolic gases in readily assimilable state. However, the planktonic ways of life have evolved to accommodate the several problems and drawbacks associated with living in open water. These concern (1) remaining in suspension, (2) exploiting nutrient resources, and (3) energy.

Specific gravity of planktonic organisms is typically higher than that of the water. Therefore, in calm water, planktonic organisms will ultimately sink. Evolution of plankton was largely driven by overcoming sinking loss and includes a number of mechanisms (active movements by means of flagella, cilia, contracting cells/tissues, shape, gas vacuoles, chemical composition of storage materials, decreasing sinking loss by developing complex forms to increase form resistance; Padisák *et al.*, 2003a, b).

Concentrations of obligate material components of living cells, especially the aqueous concentrations of some of these (especially carbon, nitrogen, phosphorus, iron, and 15 or so micronutrient elements) are often so dilute that their availabilities place a severe constraint on the assembly of planktonic biomass. Moreover, the absorbance of solar energy by

pure water is such that, at depths of > 100 m it is always as dark as night. Biological productivity in lakes is often severely constrained by rarefied resources or by deficiencies in processing energy, or by both. Far from being an ideal environment, the pelagic is a rather unpromising medium for successful exploitation by living communities.

Yet, within this general constraint, there is a remarkable richness of individual species inhabiting the plankton of the world's lakes and seas. As a preface to the planktonic biota, it is necessary to emphasize that the familiar separation, first of plants and animals and then their subdivision among phyletic divisions, cannot be applied too rigidly. The convenience of distinguishing planktonic "plants" and "animals" by function does not necessarily correspond to any fundamental evolutionary or phyletic separation. The first attempts at describing planktonic diversity by tools of molecular genetics resulted in recognition of much higher number of heterotrophic protists than was revealed by microscopic methods (Luo *et al.*, 2011). The perplexity is yet greater when referring to the bacteria: Although the lack of a membrane-bound nucleus and of certain other intracellular organelles provides a robust separation of their prokaryotic organization from the cells of eukaryotes, it is still difficult to distinguish among most bacteria other than by their biochemical activities and their affinities at the molecular level. Relatively "safe ground" is reached only among the more distinctive metazoan phyla, though even there, affinities among the main groups are often still obscure.

The Structure of Planktonic Communities

Phytoplankton is extremely diverse. More than 4000 species of marine phytoplankton have been named and described (Sournia *et al.*, 1991). The total number recorded from inland waters is not certainly known, but it is estimated that there are about 4000 of these as well (Reynolds, 1996). Few genera and still fewer species are common to both fresh and salt waters. The purple (Chromatiaceae) and green sulfur bacteria (Chlorobiaceae) are represented in specialized, anoxic habitats. Of the planktonic genera of cyanoprokaryotes (formerly classed as Cyanophyceae, or "blue green algae," and now most commonly referred to as Cyanobacteria), most occur in lakes, though several are also common in the low-salinity (< 11 parts per thousand) areas of the Baltic. The cyanoprokaryotes are also well represented among the smallest marine and freshwater primary producers (the picophytoplankton: cells $< 2 \mu\text{m}$ in diameter; Waterbury *et al.*, 1979; Callieri, 2008).

The more conspicuous components of the phytoplankton of the open sea belong to the Pyrrophyta (including a wide variety of dinoflagellate species) and Heterokontophyta. The latter large division is taken to include the large number of diatom species and the diversity of elaborate, scale-bearing Coccolithophorids is also remarkable. Besides diatoms and Cyanoprokaryotes, the more conspicuous components of the freshwater phytoplankton may be contributed from among the many chlorophyte and chrysophyte orders. However, cryptomonads, peridiniids, chloromonads, and euglenoids can all occur in large numbers at certain locations (Krienitz, 2009).

The number of species represented in the marine zooplankton of the sea is considerably enriched by the distinctive dispersal stages of many marine animals that spend their adult lives in the littoral or the benthos. To differing extents, these larvae (the amphiblastulae of sponges, the medusae and ephyrae of the cnidarian coelenterates, the pilidia of nemerteans, the trochospheres of polychaetes, the cypris larvae of cirripedes, the phyllosomae and zoeae of the eucarid malacostraca, the veligers of the lamellibranch mollusks, the various auriculariae, bipinnariae, and plutei of the echinoderms, and the appendicularian larvae of the ascidians) share the diminutive size ranges and feeble swimming movements characteristic of the species which are planktonic throughout their lives. The microzooplankton fraction (in the size range, $20\text{--}200 \mu\text{m}$) includes the rhizopod foraminiferans and radiolarians, and a range of ciliate and suctorian ciliophorans. More conspicuous ($0.2\text{--}20$ mm) in the marine zooplankton are the ctenophoran "comb jellies" and sea-gooseberries, the chaetognath "arrow worms," some specialized turbellarians and polychaetes, certain opisthobranch gastropods, and the larvaceans and salps.

The most prominent of the animals of the marine plankton, however, are crustaceans. Most of the species are copepods, including calanoids and cyclopoids. There are also some representative cladoceran and ostracod genera. The malacostracan orders are distinctively represented by organisms that remain planktonic in their adult stages. Mysidaceans are locally abundant and a few cumaceans are remarkable for being nocturnally planktonic and diurnally benthic in coastal waters. Perhaps the most renowned component of the plankton of the high-latitude oceans, mainly for being one of the major food sources of the filter-feeding whales, is krill (*Euphausia* spp.). Some of the cnidarian jellyfish may be regarded as being the largest animals in the plankton (> 20 mm, perhaps to 2 m). Though some of these are rather larger than some of the swimming organisms ("nekton": fish, cephalopods) that are excluded from the understanding of "plankton" (discussed earlier), the large jellyfish qualify for their poor ability to control their own movements in the sea.

Finally, the young stages of several species of pelagic fish are of such diminutive size and swim so feebly and with weakness of motility that, for the first part of their lives, they are reasonably included among the plankton.

The phyletic representation in the freshwater zooplankton (Havel, 2009; Rudstam, 2009; Wallace and Smith, 2009; Williamson and Reid, 2009) is known to be relatively much poorer than in the sea, but this reflects mostly the poorer representation of the animal phyla among freshwaters. Protists usually figure prominently in the plankton of inland waters, supposedly as a function of the organic matter available, including detrital particles and their associated bacteria. The smaller heterotrophic flagellates generally consume free-living bacteria, but many of the common planktonic microciliates, like *Coleps* and *Tintinnidium*, feed also on small algae and flagellates. In doing so, they fulfill an important linkage in the so-called microbial loop (Azam *et al.*, 1983; Fenchel, 2008): In many systems, the excretion of excess organic carbon fixed in photosynthesis, its assimilation by bacteria and its successive transfer through closely coupled flagellate-ciliate consortial linkages to copepod consumers and, eventually, planktivorous

fish, demonstrably exceeds the carbon transfers along the conventional phytoplankton → zooplankton → fish trophic pathway (grazing chain). Planktonic fungi (especially chytrids) feeding on large sized, ungrazeable phytoplankton species are linked to the trophic system as a “mycoloop” sometimes retaining considerable amount of carbon in the pelagic systems (Kagami *et al.*, 2007).

Occasionally, the larger Amoeboae and ciliates may dominate the zooplankton; this may owe to the prevalence of a particular food source, or to the fact that a crustacean plankton has not yet developed, or that some other factor (e.g., low oxygen concentration) restrains potential competitors for the same food resource.

At least two freshwater coelenterate genera have planktonic medusae. The Gastrotricha phylum of minute, wormlike but unsegmented animals is occasionally represented by planktonic specimens. Rotatoria is prominently represented in the freshwater plankton by some two dozen genera. The most ecologically important genera include *Asplanchna*, *Brachionus*, *Filinia*, *Keratella*, *Kellicottia*, and *Synchaeta*. Some are specialist feeders; most of those mentioned browse or filter-feed on bacteria, detritus, and planktonic algae, generally within species-specific size ranges (Pourriot, 1977).

As in the sea, the most prominent planktonic animals are crustaceans. The branchiopods are represented by the anostracan “brine shrimps,” especially in temporary waters, and by the Cladocera, the familiar “water fleas.” This grouping (its monophyletic origin is now doubted) includes the mainly herbivorous, filter-feeding species of *Daphnia*, *Ceriodaphnia*, *Moina*, *Simocephalus*, *Bosmina*, and *Holopedium*, and the predatory *Bythotrephes* and *Leptodora*. Planktonic ostracods are noted in lakes in Southeast Asia (*Cypria javensis*) and in Laguna de Petén, Guatemala (*Cypria petenensis*). The copepods are particularly well represented by calanoids (such as *Eudiaptomus*, *Eurytemora*, and *Boeckella*) and by cyclopoids (e.g., *Mesocyclops*); some parasitic cyclopoids (e.g., *Ergasilus*) are dispersed through the plankton. The branchiurans (e.g., *Argulus*), which are ectoparasitic on open-water fish, are certainly considered essentially planktonic. Though principally marine, the mysids are represented in the plankton of several high-latitude lake systems, where *Mysis* is regarded as a relict from the last glaciation. The Amphipod flag is carried by *Macrohectopus*, which is endemic to the plankton of Baykal Lake.

Among the arthropod insects, several genera of Diptera have larvae, which pass most of their time in the plankton. The most specialized of these are the juvenile chaoborines (e.g., *Chaoborus*) or phantom midges, whose transparent bodies reveal the internal provision of buoyancy-providing air sacs. The dispersal stages of aquatic larvae of other orders of insects sometimes show adaptations that are unmistakably planktonic: A striking instance is provided by the first instars of *Sialis* (Megaloptera; see Elliott, 1996).

Explaining Species Diversity

The foregoing passages confirm the richness of phyletic representation and the very large number of individual species that collectively contribute to the overall diversity of

planktonic organisms. At one level, we might be surprised that this problem arises at all. It should not be unreasonable at all to anticipate that in a supposedly fluid and isotropic medium, fully accessible to suitably adapted species, Darwinian selection should move the structure of the assemblage toward just a small number of specialists, each being the best-fit survivor in its key community role. Every less-fit competitor might be supposed to suffer progressive exclusion by the stronger species; overall, diversity should be suppressed. Thus, to confront the remarkable richness of planktonic plant and animal species surveyed previously, is counterintuitive and paradoxical (Hutchinson, 1961).

Many theories have been advanced to explain Hutchinson’s (1961) paradox of the plankton, but the conundrum for a long time remained unsolved. Either the number of occupiable niches must be far more numerous than had been supposed or the competition was somehow incomplete in its effects.

Hutchinson himself suspected that the assumption of a homogeneous environment with steady-state properties was flawed. Collectively, the environments that planktonic populations inhabit are subject to huge variability in their chemical makeup and in their physical characters. They may be physically separated from each other (as are freshwater catchments), enjoying quite different climates or, even if contiguous (like the seas), their systems may be close to mutual isolation by currents and circulations. On the continents, lake basins are created and destroyed at, relative to evolutionary rates, high frequency. The skeletal understanding of the history of the world’s oceans is that they have undergone large oscillations in metabolism and productivity associated with changes in the biospheric carbon cycles (Thierstein, 1989). Superimposed on the longer term changes are relatively higher frequencies of periodic forcing. Within these smaller habitat units, the higher frequency environmental oscillations might lead to alternations in the favored specialisms and consequent interspecific transfers of competitive advantage. Physical limitation of range (endemism) or otherwise (cosmopolitanism) would then represent the two extremes of dispersal efficiency across physical barriers and habitat preferences.

Current understanding of plankton ecology conforms to this general view in that it is certainly possible for the experienced observer to determine the broad habitat provenance of given planktonic assemblages: Their species composition has an indicative value because similar assemblages characterize similar pieces of water. Most university textbooks accepted a prevailing view that planktonic species are generally cosmopolitan and disperse freely, so that, on balance, most are able to establish quickly wherever suitable conditions arise. Dispersal mechanisms among the protists and prokaryotes are certainly effective (Padisák, 2009), and it is true that many conventionally identified morphotypes enjoy worldwide distributions. As more molecular information becomes available, the cosmopolitan nature of plankton is increasingly called into question. Besides, the notion that “everything is everywhere” is surely a matter of degree: Ease and frequency of dispersal are not equal among planktonic species. Isolation and regional endemism occur (Tyler, 1996), especially where long physical distances or significant hostile

barriers separate sites of suitable habitat. It often takes anthropogenic intervention to bridge these gaps, as the recent “breakout” of the lamellibranch, *Dreissena polymorpha*, and hitherto endemic mysids from their original Caspian-basin locations into the waterways of Europe and, now, North America graphically reminds us. Equally remarkable is the arrival of the first freshwater Cladocera on Easter Island in 1780, which had failed to bridge the distance from the next nearest lake (more than 3000 km distant) prior to Captain James Cook’s requirement to replenish his ship’s supply of drinking water (Dumont, 1999). Energetic field naturalists carrying algae on their plankton nets from one lake to another can also be efficient dispersal agents (Talling, 1951).

Planktonic communities change frequently and fast within individual years. The differential responses of individual species of plankton to temperature, day length, or nutrient resources are generally recognized to underpin what is perhaps the most familiar feature of planktonic communities – the so-called seasonal succession. As with other aspects of plankton ecology, the identity of its driving variables has been actively pursued and described by conceptual word models; the most compelling of these has been the PEG-model of Sommer *et al.* (1986). It is founded on an implicit acceptance of the differences among planktonic species and the suitability of species-specific adaptations to particular habitat constraints.

The way to explain planktonic biodiversity is through a simultaneous recognition of the variables constraining habitat suitability and the adaptive specialisms and limitations of species for which the habitat constraints will select and those against which they will discriminate.

Habitat Constraints in the Plankton

The assumption of a uniform, hospitable steady state is erroneous so far as most open-water habitats are concerned. On the contrary, many are as hostile as their desert-like barrenness conveys. Relative infertility may be locally or regionally attributable to an inadequacy of light energy to sustain planktonic primary production and the import of organic carbon is too modest to support the heterotrophs. Light income may be scarce for reasons of latitude (e.g., short day length and low solar declination), or it may be severely “diluted” over a deep mixed layer, or its penetration may be abruptly curtailed by a high concentration of inert particles (turbidity). Commonly, the concentrations of assimilable sources of certain primary nutrients place a very low ceiling on the biomass that can be assembled (nitrogen, phosphorus, and iron are cited most frequently as capacity-limiting factors). For the planktonic animals, the problem is to be able to forage sufficient food; the concentrations and the size distributions of potential food particles influence profoundly the nature and abundance of the consumer populations.

Besides the spatial differentiation of planktonic habitats, there is usually a considerable temporal variability. Conspicuous are the seasonal changes consequent on latitude: Lengthening spring days and higher flux densities are generic to all temperate ecosystems but for small organisms with short life spans, for example, the changes are perceived by successive generations and not as some perennial amplitude

of fluctuation registered by a forest tree. The onset of thermal stratification, as a consequence of a shifting balance between the buoyancy forces brought through surface warming and the kinetic dissipation of the work of wind energy, precipitates a train of environmental effects leading to enhancement of the segregation of the warm, insulated, aerated, and increasingly resource-depleted epilimnion from a colder, darker, and potentially less oxidizing hypolimnion. Also, such seasonality is not confined to high latitudes: Even quite small differences in wind prevalence, cloud cover, humidity, and hydraulic exchange result in seasonal variations in thermal stability and downmixing in the tropics (e.g., see Talling and Lemoalle, 1998), and convectional currents generated by day–night temperature differences (atelmixis, see Lewis, 1973) may lead to selection of species that are particularly adapted to this environment (functional group N_A , see Souza *et al.*, 2008).

So it is that the different kinds of water bodies (lake or pond, river, estuary, coastal shelf, upwelling, or the open oceans) offer, to the most appropriately adapted species, or to those simply furnishing the largest inocula, varied and sometimes very transient opportunities to build their local populations. Furthermore, because the medium is fluid and the movement induced by wind or gravity is subject to fluctuations in strength, the persistence and vertical extent of an upper differentiated layer is a highly variable character of the environment, which alters not just from season to season but also from day to day and from hour to hour. Interest is also growing in the effect of year-to-year variations. These might be the result of mesoclimatic variability acting through salinity (Padisák, 1998) or extension of ice-cover (Padisák *et al.*, 2010) fluctuating over decadal scales.

It follows that selective advantage is likely to move among species. Environmental variability is a powerful influence on the assembly of planktonic communities and thus on their biological diversity. The causal linkages between observable patterns and processes in the maintenance of species diversity in the plankton may be usefully explored through a diagrammatic representation of the two principal variables characterizing particular open-water environments, namely, the fluctuating fluidity or vertical extent of the uppermost water layer and the availability of the resources to support the assembly of biomass. The layout of Figure 1 is descended from Margalef’s (1978) original scheme for marine phytoplankton, in which a “nutrient” axis is set against one of “turbulence;” the arrangement is amenable to tracking habitat variability and the changing species composition through time. The scheme has been developed for freshwaters to accommodate habitat conditions in which nutrient resources and the light availability in the surface-mixed layer are sufficient to saturate the fastest *in situ* algal growth rates (in the top left corner of Figure 1) and to distinguish them from conditions that become either increasingly resource-constrained (moving downward in the matrix) or increasingly energy-deprived (moving rightward), or fall deficient in both (bottom right corner). The selection of given species or groups of species was found broadly to be correlated with the matrix space thus represented; high-performance, fast-growing algae would be favored in the relative paradise of the upper left-hand corner; algae favored by the second and third contingencies show some specialist adaptations, respectively, for operating under

Figure 1 Two-dimensional representation of limnetic habitats, which, starting in the top left, distinguishes well-insolated, resource-replete water masses from (working down) long-stratified, resource-segregated water columns and from (working across) increasingly light-deficient environments.

conditions of low concentrations and remote sources of nutrients, or for harvesting light from low irradiances or from infrequent short periods in the light field. The fourth, low-nutrient, low-light contingency is unfilled and is something of a phycological desert, evidently untenable as a habitat for a photoautotroph (Reynolds, 1988b).

Effort has been invested to improve both the utility and the quantification of the axes. The horizontal axis in **Figure 1** describes the integral, I^{**} , which, as the product of the physical depth of mixing and the vertical attenuation of a finite input of light energy, is sensitive to the constraints of both deep mixing and high turbidity; quantities diminish rightward on a logarithmic scale. The vertical axis in **Figure 1** accommodates another composite scale, K^{**} , being the quotient of the concentration of the critical nutrient in the medium (usually the surface-mixed layer) and the gradient of concentration between the top and bottom of the entire trophogenic layer. This scheme differentiates sites that are chronically deficient in nutrients (points plotted well down the K^{**} axis) from, on the one hand, those in which steep gradients develop as a consequence of near-surface uptake (points track from high to low on the K^{**} axis) and, on the other, those in which the nutrient is scarcely exhausted (points located consistently toward the top of the K^{**} axis).

Against these axes, it is possible to characterize the “signatures” of seasonal changes in various kinds of water body, including of small, “eutrophic” lakes, in which nutrient availability is seasonally reduced, of shallow, fertile systems, in which the turbidity is the predominant variable, and of deeper, oligotrophic systems, where the depth of mixing is the strongest seasonal variable. An analogous (and in many ways, a more self-evident) approach has been developed for the sea (**Figure 2**). This distinguishes energy-limited, well-mixed, high-latitude oceans from the highly stratified, nutrient-segregated waters of the tropics and will represent processes and interactions in coastal and shelf waters, including frontal zones and major upwellings of deep circulation currents.

Form, Function, and Selection in the Phytoplankton

The essential environmental requirements of planktonic photoautotrophs, to be able to grow in numbers and increase in total biomass, do not differ fundamentally from those of plants in other ecosystems: Access to water, exposure to adequate levels of photosynthetically active wavelengths of light, a source of assimilable carbon and adequate supplies of each of a score of other elements. In the dilute world of the plankton, diffusion alone is rarely able to supply the resource requirements of plankton. Adaptive mechanisms for gathering chronically deficient resources include the enhancement of uptake affinity and of the maximization of storage. Mechanisms enhancing access to remote reserves or for exploiting alternative sources of nutrients are valuable against a depleting resource base.

The distinguishing feature of the photoautotroph is the ability to first generate the carbohydrate through the photosynthetic reduction of carbon dioxide. The energy to do this comes from sunlight. Because of the sharp underwater attenuation of downwelling sunlight, only the near-surface layer is readily supportive of net primary production. Even then, seasonal, diurnal, and weather-determined fluctuations in the intensity and duration of incident sunshine means that the spatial and temporal extent of this euphotic layer is highly variable. To operate habitually at more rarefied light levels clearly requires the provision of more, or more efficient, light-harvesting capacity. Moreover, because it is frequently the case that the depth of the wind-mixed layer extends beyond the euphotic layer, convective entrainment of phytoplankton often diminishes its aggregate exposure to the light field, at times leaving cells unable even to compensate their basic metabolic energy requirement. At the same time, the planktonic photoautotroph still needs a suite of biochemical and physiological defenses to deal with the risk of overexposure of enhanced light.

Assuming the theoretical output of 1 mol of reduced carbon for the investment of 8 mol photons of photosynthetically

Figure 2 Two-dimensional representation of some marine habitats, which separates the mixed (light deficient) and well-stratified (nutrient-segregated) from shallow, nutrient-rich shelf waters, as well as upwellings and frontal zones. As in **Figure 1**, moving away from the top left corner, habitats become increasingly resource-stressed (working down) or processing-limited (working across). Toward the bottom right (beyond the diagonal), habitats are ultimately untenable to photosynthetic autotrophs.

active radiation harvested, taking an average 50 : 1 carbon-to-chlorophyll ratio, exponential cell-specific growth capacities of $0.04\text{--}0.26\text{ h}^{-1}$ may be deduced, which potentially might support biomass doublings from one every 17 h to one every 3 h.

For such rates of cell replication to be realized and sustained, not only must the light levels and the carbon dioxide supply be upheld, but also all the other chemical resources have to be available in concentrations that will also saturate the uptake demand. For instance, the widely accepted stoichiometry of Redfield (1958) leads us to suppose that for every 42 mg C incorporated, the new generation would, ideally, also require roughly 1 mg P and 7 mg N if the normal cell stoichiometry was to be preserved. Such theoretical calculations of the stoichiometric capacities are helpful to the identification of which of them is most likely to set the constraint on growth generally and, hence, that to variations in which will evoke the most sensitive changes in growth rate and supportable biomass. In many kinds of lakes and seas, the total annual area-specific loads (including recycled nutrient) of either nitrogen or phosphorus or both fall far short of the respective hypothesized saturation requirements.

It is possible to show consistent morphological and adaptive traits among phytoplankton species that are variously exploitative, disturbance tolerant, and stress tolerant. It is also possible to quantify the impacts of adaptation and to demonstrate the satisfying coherence among the form, function, and ecology of planktonic algae (Reynolds, 1988b, 1995). For example, the species that appear in “new water

bodies” (from rain puddles to tidal pools), in hydraulically (flood plain lakes after the river drops back) or seasonally refreshed systems (lakes at the onset of thermal stratification) are typically characterized by an ability for rapid growth. Typical freshwater representatives include such algae as *Chlorella*, *Koliella*, *Chlamydomonas*, *Rhodomonas*, and *Chrysochromulina*. They are unicellular or form small coenobia (generally $<10^3\text{ }\mu\text{m}^3$), offering a surface/volume ratio ($>0.5\text{ }\mu\text{m}^{-1}$) favorable to rapid solute exchange and nutrient assimilation. The area (e.g., of light field) projected by the algal cell mass, usually a mark of its potential efficiency as a light-gathering antenna, is equivalent to at least 6.5 m^2 (mol cell C^{-1}). Reynolds (1995) proposed that these traits were indicative of an “invasive” or, in the terminology of Grime (1979), C-type life-history strategy.

The adaptations that help species to survive developing nutrient stress include the physiological flexibility to overcome deficiencies in the supply of carbon (such as the ingestion of bacteria by the facultatively phagotrophic dinoflagellates and chromulines), nitrogen (“fixing” the gas dissolved in the water, as occurs in the facultatively produced heterocytes of Nostocalean Cyanobacteria), and phosphorus (producing osmotically inactive polyphosphates). The ability to conserve assembled biomass through reduction in sedimentary and grazing losses is contributed by combining motility (usually swimming) with large size: Ease of disentrainment and self-regulated migratory ranges give access to resources in the remoter parts of the water column that may be denied to smaller species. Freshwater examples (which include larger species of

Peridinium, *Ceratium*, *Microcystis*, and other colonial, bloom-forming Cyanobacteria and, arguably, such colony-forming algae as *Uroglea*, are characteristically “large,” having cells or coenobia that are $> 10^4 \mu\text{m}^3$ in volume and often much more than $30 \mu\text{m}$ in diameter. Their consequent rather low surface/volume ratios ($< 0.2 \mu\text{m}^{-1}$) leave the algae with slow rates of growth ($< 8 \times 10^{-6} \text{s}^{-1}$ at 20°C), sensitivity to low temperatures, and poor antennal projection ($\leq 2.5 \text{m}^2(\text{mol cell C})^{-1}$). The occurrence of growing populations of these stress-tolerant – S-type, (or “acquisitive;” Reynolds, 1995) – strategists, tends to be restricted mainly to warm, well-insolated shallow lakes and epilimnia.

The phytoplankton species tolerant of, if not dependent on, near-continuous entrainment within deep or turbid mixed layers have well-developed capabilities for maintaining growth despite intermittent brief exposure to light. “Attuning” (Reynolds, 1995) strategists tolerate this scale of pelagic disturbance through the projection of a large mass-specific surface area ($> 8 \text{m}^2(\text{mol cell C})^{-1}$ in the case of 1-mm threads of *Planktothrix agardhii* and $\sim 30 \text{m}^2(\text{mol cell C})^{-1}$ in the case of an eight-celled colony of *Asterionella formosa*). They have high surface-to-volume ratios (generally $> 0.5 \mu\text{m}^{-1}$) though these are not necessarily attained through small unit-size but by morphological complexity (filaments, attenuated or fenestrated coenobia, protuberances, etc.) and so continue to benefit from reasonably rapid rates of cell-specific nutrient uptake and growth. The potential for energy conversion may be enhanced by an increased cell-specific chlorophyll content and accessory pigmentation to widen the spectrum of harvestable wavelengths.

Not all phytoplankton species fit perfectly within one or other of the three categories; some show properties intermediate between them. What is interesting, however, is that the intermediacy in morphological and physiological adaptation matches well the intermediacy in their ecologies. The “space” between the invasive and the stress-tolerant acquisitive species is occupied by genera such as *Dinobryon*, *Dictyosphaerium*, *Sphaerocystis*, *Gemellacystis*, arguably *Volvox*, *Eudorina*, *Aphanizomenon*, and *Gloeotrichia*, which diminish in surface area/volume ratio and maximum growth rate but increase in their abilities to exploit and conserve nutrient resources. Freshwater algae between the invasive and the attuning poles include species of *Cyclotella*, *Scenedesmus*, and *Coelastrum*, which could be said to be increasingly large, more convoluted, and increasingly disturbance–turbidity-tolerant algae. The axis between stress- and disturbance-tolerance is occupied by relatively large, acquisitive, but self-regulating species, which can persist for months to years on stable density gradients, notably *Planktothrix rubescens* and other cyanoprokaryotes including the notorious *Cylindrospermopsis raciborskii* (Padisák et al., 2003c).

Despite its celebrated species richness, the phytoplankton is usually dominated by very few genera at a time (it has been suggested that 95% of the extant standing biomass will be incorporated in no more than eight species at any one time; often it will be in rather fewer, as few as one or two; Reynolds, 1997). Yet it is well recognized that the dominance moves among different species through time and that, in a given system, the sequence will be similar from one calendar year to the next. Moreover, similar patterns may be observed in

similar but often geographically remote lakes. Numerous such cycles have been described in the literature (Reynolds, 1984; Sommer et al., 1986). No two years will be exactly the same, and the relative proportions of simultaneously dominant and codominant species will fluctuate.

Preliminary considerations of the types of phytoplankton characterizing the various subdivisions of the sea do reveal parallel trends between morphology and performance. For instance, as days lengthen over the open seas of the temperate latitudes, an initial typical spring bloom of such chain-forming diatoms as *Thalassiosira nordenskioldi*, *Skeletonema costatum*, and *Chaetoceros* (all manifestly having R-type, attuning characters) gives place in summer to relatively large, motile, S-like peridinians (e.g., *Scrippsiella trochoidea*) and ceratians (e.g., *Ceratium tripos*), which are often followed, in autumn, by chain-forming (*Chaetoceros* spp.) diatoms with high surface-area-to-volume ratios and antennal enhancement. In the high-nutrient, high-energy waters of coastal margins, potential dominants are generally small, usually unicellular, centric diatoms (e.g., *Cyclotella caspia* and *Thalassiosira weissflogii*), green flagellates (e.g., *Dunaliella* and *Nannochloris*), euglenoids (*Eutreptia*), and gymnodinioids (*Gymnodinium*); all qualify as fast-growing opportunist (C-) species. The estuarine prorocentroids are also conspicuous. Blooms of *Phaeocystis* may follow, before giving place to ceratians. In the highly stratified, tropical oceans, dominance passes quickly from diatoms to *Emiliana* and to the large *Ceratium* spp. and *Ornithocercus*. The big, buoyancy-regulating, stress-tolerant, S-species of diatom (*Ethmodiscus*) and dinoflagellate (*Pyrocystis*) are at the culmination of this sequence.

Spatial differences – among latitudes or between neritic shelf waters and the open oceanic systems – probably also attest to the functional differentiation of the phytoplankton. Areas of frontal activity and of surface upwellings of the deep oceanic circulation currents tend to combine intensive mixing with renewed resources and to select species in the C–R intermedium through much of the year: *Gyrodinium* spp., *Alexandrium tamarense*, and *Thalassiosira leptoporous* can be typical assemblage members. Away from the epicenters of the upwelling areas and where, indeed, the water is less mixed but still charged with nutrients, such taxa as *Dinophysis*, *Gonyaulax* and *Gymnodinium catenatum* provide prominent markers of the (R–S) transition between stressed and disturbed conditions.

The functional group concept in phytoplankton was initiated by Reynolds (1980), and after some modifications (Reynolds, 1984) it was published in full detail.

Two main ideas lie beneath the functional groups theory: (1) a functionally well-adapted species is likely to tolerate the constraining conditions of factor deficiency more successfully than individuals of a less well-adapted species; (2) a habitat shown typically to be constrained by light, P, C, N, or whatever, is more likely to be populated by species with the appropriate adaptations to be able to function there (this of course does not imply that those species will be there). As a consequence, the term “functional group” is sensitive to the sets of appropriate adaptive specialisms and the clusters of species that exhibit them.

The article “Toward a functional classification of the freshwater phytoplankton” published in 2002 by Reynolds

and coauthors has received a great deal of attention from phytoplankton ecologists.

Until now, 37 functional groups are described (Padisák *et al.*, 2009) and the application of the concept to monitoring purposes is also developed (Padisák *et al.*, 2006; Borics *et al.*, 2007). Though splitting species into different functional groups requires good taxonomic skills and a deep knowledge of the autoecology of single species or species groups, application of the functional group concept is being applied to an increasing extent.

Form, Function, and Selection in the Zooplankton

In terms of species success, the survival strategies, and selective biases, the ecological constraints governing the lives of zooplankton are wholly analogous to those acting on the phytoplankton. In the case of a heterotroph, additional energy is consumed in the foraging of foods – the essential requirement is that the investment of energy yields a greater return of potential energy in the organic carbon thus derived. Resource gathering carries a high energy demand: “Maintenance costs” of phagotrophs are proportionately high, not untypically accounting for some 90% of the resources consumed. Specific requirements differ substantially, as do the time-scales over which the organisms respond to environmental fluctuations.

The size range of planktonic animals embraces the flagellated protists, whose dimensions leave them substantially embedded within the viscous range of aquatic environments, through to crustaceans and young fish whose lives reach well into the turbulent range. Although the former rely on encounters of suitable food particles (organic detritus, not necessarily autochthonous, bacteria, small algae) within the same viscous neighborhood, animals living mainly within the boundaries of the turbulent world have a modicum of control over their own movements.

There is also considerable differentiation among the strategies for survival and resource exploitation. In addition, predation by planktivorous fish and invertebrates has a central role in structuring zooplankton assemblages: Although larger animals ostensibly have more foraging opportunities for a wider choice of potential foods, they are also more vulnerable to visual predators (Brooks and Dodson, 1965; Hall *et al.*, 1976). Romanovsky's (1985) analysis of life-history strategies of the planktonic Cladocera distinguished among those species that invest in high survivorship rather than in rapid juvenile growth (exemplified by *Diaphanosoma brachyurum*), those ultimately large-bodied species that sustain rapid rates of juvenile recruitment and development (typified by *Daphnia hyalina*), and those smaller-bodied, fast-reproducing inhabitants exploiting the fluctuating opportunities of temporary ponds and water bodies (including species of *Moina*). Taking particular account of the interspecific trait variability in adult cladoceran size and the negative correlations (“consistent trade-offs”) between egg number and yolk investment and between larval development time and resistance to starvation, Romanovsky recognized three basic life-history strategies. He referred to these as being “patient,” “violent,” or “explerent.” It needs little insight, however, to

recognize that this imaginative perception is but a quite independent assessment of the expression of “resource-stress tolerance,” “exploitative invasiveness,” and “disturbance tolerance” among animals. In this way, it is possible to fit planktonic animals to a habitat template, analogous to that for the phytoplankton, on the basis of a wholly functional classification.

Zooplankton of the open seas and of larger oligotrophic lakes live in environments where the producer biomass is chronically resource limited: The potential food resources for zooplankton (planktonic algae, bacteria, and particulate organic detritus) are generally $<0.1 \text{ g C m}^{-3}$. To be successful under persistent conditions of dilute resource, animals must blend energy-efficient foraging with controlled resource exploitation – they must adopt the “patient” strategy of resource-stress tolerance, especially with respect to the recruitment of juveniles. Investment in a small number of relatively large eggs with a relatively long development time is typical. Physical and behavioral defenses reduce the vulnerability to predation. Such traits distinguish the life histories not only of *Diaphanosoma* but also of many of the calanoid copepods. The sophisticated browsing mode of feeding that they adopt has been shown to be sufficient to sustain natural populations and support their reproduction at food concentrations in a range equivalent to $0.01\text{--}0.08 \text{ g C m}^{-3}$ in both the sea (Huntley and Lopez, 1992) and lakes (Hart, 1996). Arguably, the ciliates (e.g., *Halteria* and *Strombidium*), which constitute a significant part of the diet of calanoids in oligotrophic lakes, must be, similarly, stress-tolerant patient strategists.

In the more productive waters of fertile lakes and rivers, estuaries, nutrient-enriched coastal-shelf waters, and oceanic upwellings, the capacity to support autotrophic biomass may, for at least some of the time, significantly exceed 0.1 g C m^{-3} . This is an approximate threshold, above which the energetic return from filter-feeding becomes steadily more favorable. Among lakes, for example, daphniids tend to become much more abundant, absolutely, and relative to calanoids. Most species of *Daphnia*, when adequately nourished, are able to grow and mature rapidly to increase egg production and to recruit the next filter-feeding generation over a few days (George and Reynolds, 1997). The 12-fold increase in the *Daphnia*-dominated community-filtration rate in 13 days, measured by Reynolds *et al.* (1982; note, aggregate filtration capacity doubles every 3–4 days), conforms to the understanding of an exploitative, or “violent,” life-history strategy. Among the noncrustaceans, the ciliates of microaerophilous environments (e.g., *Metopus* and *Caenomorpha*) react in an analogous way to food abundance in media from which other sorts of consumer are mainly excluded.

Many noncrustacean members of the zooplankton take advantage of short generation times to track bursts of algal or bacterial abundance. Protists including *Diffugia*, *Coleps*, *Tintinnidium*, and *Nassula* and rotifers such as *Keratella*, *Kellicottia*, and *Brachionus* will often respond to an expansion in suitable algal foods, but this occurs before the daphniids can ascend to dominance. Their disturbance-accommodating life-styles are well suited to the direct exploitation of small phytoplankton and organic detritus in the middle reaches of large rivers, provided travel times permit (Viroux, 1997).

Function in the Bacterioplankton

Microbial populations constitute the third integral component of the planktonic communities of lakes and seas, where they are often numerous (typically within the range 10^5 – 10^7 cells ml^{-1}). Microbial diversity, however, is not yet well understood, principally because the bacterial taxa are still insufficiently distinguishable to be separated routinely to species level. Given that, for most of them, the utilization of dissolved reduced-carbon substrates provides the main source of energy, even the functional approach appears to have its limitations for bacterioplankton. “Organic carbon compounds” are derived from a very wide range of the breakdown products of biogenic materials, many originating from the land, as well as a host of very unnatural anthropogenic organic substances. The ability to break down particular classes of compounds or kinds of bonds is unlikely to be shared by all bacteria. Every such process presumably requires the action of one or more discrete enzymes, and the ability to produce each enzyme requires one or more genes dedicated to its production. As the genetic complement of microbes is relatively modest, it follows that the number of separate, substrate-specific bacterial strains is likely to be high.

Modern molecular approaches are slowly sorting out “who does what” but, for the present, the diversity of the bacterioplankton is anticipated to be high.

In smaller lakes and ponds, the nature and diversity of organic carbon sources are enriched by direct transport of biogenic materials from the catchment area. However, current understanding is also having to accommodate the recognition that often the largest fraction of organic carbon present in stream and lake waters comprises plant-derived humic and fulvic acids washed in from catchment soils (Wetzel, 1995). They are particularly abundant in brown and “black” waters draining forests and peatlands. The relative size of this fraction indicates its high resistance to microbial breakdown. Refractory dissolved organic carbon from terrestrial sources break down slowly; some is rendered labile by exposure to ultraviolet radiation.

In the microaerophilous environments of the bottom sediments and in the deep water of stratified, productive lakes, anaerobic microbes are common and typically numerous; they include *Clostridium*, the sulfate-reducing *Desulfovibrio*, and the archaean methanogens. Interacting gradients of light and of redox superimposed on relatively stable density gradients may also provide vertical sequences of microhabitats, each niche potentially differentiated according to the microorganisms it supports and whose physiological adaptations it most suits. To be able to carry out photosynthesis in a reducing environment favors *Rhodospirillum*; but to be able to use sulfide or sulfur, as photosynthetic electron donor, can bias the selection in favor of Chromatiaceae and Chlorobiaceae. The involvement of specialist chemolithotrophs in nitrification (e.g., *Nitrosomonas* and *Nitrobacter*) and in the oxidation of sulfur (e.g., *Thiobacillus* and *Beggiatoa*) and iron compounds (e.g., *Ochromium*) further adds to the microbial diversity of freshwaters.

In the open waters of the sea, most bacteria are aerobic – relatively few anaerobes are ever found in the surface waters. Many of the same genera represented in freshwaters include

marine species: *Pseudomonas* and *Vibrio* are often found to dominate and species of *Flavobacterium*, *Alcaligenes*, and *Cytophaga* are found in high numbers (Atlas and Bartha, 1993). Sediments receiving organic inputs are bacteria-rich; moreover, where these fall anaerobic, marine sulfate-reducers and methanogens are present in substantial numbers.

In both marine and freshwaters, the vital contribution of the bacterioplankton to ecosystem function arises not only from the mineralization of organic carbon products but also from the potential remobilization and renewed bioavailability of nitrogen, phosphorus, and the metals required in the assembly of new biomass. The largely unexplored world of deep-sea hydrothermal vents may represent a substantial addition to marine bacterial biodiversity (Martin *et al.*, 2008).

Temporal Patterns in the Organization and Diversity of Planktonic Communities

Diversity is a concept drawn from communication theory (Shannon, 1948), referring to the amount of discrete information in a particular location. In communities, it could refer to the different fragments of genetic information. A diverse community is one with many different kinds of genes (species) present simultaneously. This biotic diversity (H'') can be quantified with great precision, using the specialized Shannon–Weaver function:

$$H'' = -\sum b_i/B \log_2(b_i/B)$$

Diversity increases with the number of species (s) each contributing biomass (b_i) to the total, B , in the sample of lake or seawater. The more species present, the greater is the diversity, until $H''_{\max} = \log_2 s$. In practice, it is necessary to set a bar on the efficiency of search for the rarer species (more diligent searchers would always score higher diversities). Nevertheless, the evenness of the interspecific distribution, $E = H''/H''_{\max}$, is itself a useful measure.

Local species richness (the sample, the pond, and the lake) may run to a few tens to hundreds of phytoplankton and, if the phagotrophic protists are included, perhaps 100 or so species of zooplankton. Regular sampling may raise this total considerably, as seasonal changes are encountered and the probability of encountering rare species is increased (Padisák, 1992; Padisák *et al.*, 2010). “Rare” in this context may mean one individual per liter, but there could still be a billion such individuals in a small, 10 ha lake. As observed earlier, most ($\geq 95\%$) of the total biomass of phytoplankton and that of zooplankton will each be invested in eight or fewer species. Most of the consideration of evenness concerns how the total biomass is shared among those eight. Thus, whether local species composition is species rich or otherwise, the perception of its diversity is greatly affected by the relative evenness of the most common species.

The essential step in logic that separates the niche-diversification and the persistent-disturbance theories of species richness rests on an acceptance that the supportive capacity is not always filled; conversely, although the capacity of the resources is always finite, the underexploited resource base is, by definition, *not* “limiting.” Phytoplankton

concentration is able to increase at all because, in reality, there are times when nutrient resources are available to support the additional biomass and unharvested light energy to fuel its assembly. The spring bloom, at least initially, is the response of the producer community to an expanding capacity of the resource and energy bases. Later in the year, the resource supply may well fail to meet the biological demand and severe constraints are then imposed on its further growth and maintenance. Alternatively, it is left to shortening days and convective mixing in the autumn months to erode the supportive capacity of the insolation flux.

Rapidity of growth and reproductive efficiency are crucial to the exploitative outcome: Having a large starting inoculum and, especially, a high yield/resource conversion potential is vital to the fitness of colonist and invasive species. If we judge it to be "outcompeting" the slow-growing species present, we are giving a second nuance to the word "competition." By exploiting the structure of the water column to the capacity of its resources and by continuing to grow for longer, often in the face of intensifying resource shortage, the S-type adaptive strategy allows the organisms to achieve a larger, climactic biomass than that achieved by any of the earlier invasive species. The dominance can become total, other species are effectively excluded by the ultimately superior competitor, and the Shannon diversity falls to a minimum.

Diversity within Habitats

For the geometric representation of environmental variability and of its impact on species selection, it is useful to bring the concept of fluctuation tracking back to the habitat template (of Figure 3(a)), because it is easy to relate to the environments it seeks to represent (Figures 1 and 2) and because sufficient preliminary knowledge exists about how the tracking thus represented actually selects for the preferred traits of species, at least of the freshwater phytoplankton (Figure 3(b)).

The organizational trends imposed by disturbance and stress press the selective bias toward the R or S apices of the triangular template (shown in Figure 4(a)). We have already seen that seasonal trends track through the template matrix in broad, predictable ways (summarized as S-ward and R-ward trends in Figure 4(b)), but substantial within-season variability will lead to almost chaotic short-term time tracks, such as the fragment included in Figure 4(c).

Our deduction is again that the effect of environmental variability is to move any selective advantage among species at a faster rate than opportunities narrow or that competition can forge a low-diversity monoculture dominated by a single well-adapted species. We know that this theoretical outcome, correctly anticipated by Hutchinson (1961), certainly is achievable and good descriptions of local, competitively excluded community structures are described in the literature. These cover the sort of arrested "plagioclimaces" of overwhelming *Microcystis* dominance of tropical eutrophic Lake George (Ganf and Viner, 1973) year-round and *Planktothrix* dominance of exposed, continuously mixed hypertrophic polder lakes in the Netherlands (first described by Berger, 1975). At one extremity, diversity may drop to zero, as was

Figure 3 (a) How growth conditions in a monomictic deep lake (mixed in winter) track through a calendar year, selecting sequentially for a low-light tolerant spring bloom (of R species), then opportunist C species after the onset of stratification, leading to the biologically enhanced segregation of nutrient resources tolerated by S species, before autumnal downmixing again forces conditions back toward the top right: Nutrients may be further increased (by inflow) in winter, when primary production is still increasingly light limited. (b) Some of the algal species that might be selected are shown in an analogous matrix that is based purely on shape- and size-characters of the algae concerned (sv^{-1} vs. msv^{-1} , where s is the surface area of the alga in μm^2 , v is its volume in μm^3 , and m is the maximum length dimension, in μm). A strong correlation exists between the morphologies of these algae and their functional ecologies. The algae shown are represented as follows: Ana = *Anabaena flos-aquae*, Ank = *Ankistrodesmus falcatus*, Aph = *Aphanizomenon flos-aquae*, Ast = *Asterionella formosa*, Cer = *Ceratium hirundinella*, Chla = *Chlamdomonas*, Chlo = *Chlorella*, Cry = *Cryptomonas ovata*, Din = *Dinobryon divergens*, Eud = *Eudorina unicocca*, Fra = *Fragilaria crotonensis*, Lim R = *Limnotherix redekei*, Mel = *Aulacoeira subarctica*, Mic = *Microcystis aeruginosa*, Mon = *Monodus*, Pla AG = *Planktothrix agardhii*, Per = *Peridinium cinctum*, Rho = *Rhodomonas pusilla*, Scq = *Scenedesmus quadricauda*, Sth = *Stephanodiscus hantzschii*, Syn = *Synechococcus*, Tab = *Tabellaria flocculosa*, Vol = *Volvox aureus*.

Figure 4 (a) From a starting condition, near the top left (c) corner of the triangle, environmental change moves to select increasingly for (S-) species tolerant of resource stress or for (R-) species tolerant of energy limitation (processing constraints); (b) major environmental restructuring alters the trajectory, changing the selection significantly; (c) under more frequent and perhaps less severe forcing, trajectories are redirected erratically, delaying progress to the competitive exclusion signified by the R and S apices.

observed in a small Hungarian fishpond when *Cylindrospermopsis* reached overwhelming dominance (Borics *et al.*, 2000). No less impressive is the striking commonality of organization of vertically segregated layers (or “plates”) of algal and microbial producers on the stable physicochemical gradients in permanently ice-covered lakes in Antarctica (e.g., Vincent, 1981), in tropical forest lakes (Reynolds *et al.*, 1983), and in midlatitude karstic dolines (Vicente and Miracle, 1988). However, such steady states do not occur frequently. In contrast, the great majority of assemblages that have been sampled, identified, and described in the literature are, simply, weakly organized. There need not be any paradox in this once it is appreciated that in such accumulating, mid-successional assemblages most of the specific populations are not in any steady state but rather in a state of flux, either increasing or decreasing in response to events in the recent past. Thus, most so-called communities comprise populations which, at the given point in time, are in some stage between being dismantled and reassembled.

The crucial questions about local diversity in the plankton should be “How long has it been since a restructuring was initiated by external forcing of a magnitude sufficient to create a disturbance?” and “At what rate is the restructuring taking place?” The field-scale experiments carried out in the large limnetic enclosures in Blelham Tarn, England, pointed to a progress to steady-state monocultural dominance requiring from 12 to 16 generations of the eventual dominant (Reynolds, 1988a). The time required for this could be as few as 35–60 days, provided growth rates could be sustained by water temperatures $\geq 20^\circ\text{C}$ and a supply of carbon and nutrients of a capacity to support the last population doubling. Accordingly, limitations on growth rate imposed by low temperature, slow carbon renewal, or nutrient depletion extend the generation times reciprocally, delaying the onset of the climactic condition and slowing the exclusion of diversity. More likely, the intervention of external forcing (e.g., strong winds and heavy rain) would interrupt the successional maturation at an earlier date, and if of sufficient magnitude, select for alternative species with a new target outcome. It was found consistently that the community response, represented by two to four divisions of the newly selected species simultaneously with the dieback of the erstwhile-selected species, took some 5–15 days before it was clearly manifested. It was deduced that a disturbance frequency of this magnitude (two to four

generations) is sufficient to maintain an optimal local species diversity (Reynolds, 1988a).

Analyses of temporal diversity fluctuations in small lakes in locations as far apart as Canada (Trimbee and Harris, 1983) and central Hungary (Padisák, 1993) confirm the validity of this deduction, showing diversities in phytoplankton composition peaking within 11 days of a recognized physical stimulus. These and numerous other case studies have been brought together to demonstrate this planktonic validation of Connell’s (1978) intermediate disturbance hypothesis. The essence of Connell’s hypothesis is that frequent disturbance excludes all but fast-maturing species; very infrequent disturbance allows competitive exclusion to reduce diversity; therefore, maximum diversity is maintained at intermediate frequencies. At both high and low frequencies of forcing, the numbers of intermediate species are reduced so that the inocula are no longer readily available to take advantage of conditions under which their growth might be favored. In contrast, local stocks of mid-successional species are enhanced by the sorts of opportunities that might be provided every two or three generations by the (intermediate) rejuvenation of appropriate growing conditions and with a marked alleviation of severe interspecific competition in the early postdisturbance sequel.

Species Richness Among Habitats

It can be seen that the species representation contributing the local diversity remains heavily biased toward those that have been well represented in the recent past, and which, of those whose growth should be favored by the onset of the appropriate environmental characteristics, remain potentially capable of seeding the largest inocula from standing stocks of vegetative cells and resting propagules. With the same kinds of environmental variability affecting Shannon-type species diversity in each tangible locality, there is still no clear explanation as to why the collective representation of planktonic organisms is so relatively species rich. We need a proposition for separate species representation in separated localities which recognizes that communication between localities is sufficient to maintain the high level of apparent cosmopolitanism among planktonic organisms. In other words, we need to be aware of the roles of perennation and dispersal in relation to the maintenance of biodiversity.

The survival of any species whose range of habitat suitability (as defined in the section Explaining Species Diversity) is discontinuous, in time as well as space, involves the separate development of separated populations, but with a measure of regenerative connection and gene renewal that resists their permanent divergence. The metapopulation ecology of plankton is not, formally, a well-rehearsed topic, though there have been numerous studies to contribute a general appreciation of the principles. Although the existence of liquid water on the planet has a very long geological history, individual bodies of freshwaters are extremely transient. With the exception of the basins formed by tectonic movements, a majority of these is less than 20,000 years in age. The idea of lakes as islands in a terrestrial sea is an easy one to assimilate. The actual oceans are physically and temporally contiguous, but the patterns of global circulation allow significant habitat differentiation to be maintained at the scales at which planktonic organisms live their lives. The principles of island biogeography propounded by MacArthur and Wilson (1967) provide a good model for plankton ecology.

The temporal discontinuities are most appropriately bridged by the production of resistant, resting propagules. Among the freshwater phytoplankton, almost all the major groups produce some kind of physiological resting stage, if not a discrete resting spore, cyst or akinete, some of which can remain dormant for many years and still be fully viable. Eggs may fulfill a similar role for zooplankton, maintaining banks of inocula and pending the restoration of conditions favorable to growth and recruitment of successive generations (Hairston, 1996). Produced in adequate numbers, such dormant life-history stages provide a significant survival “hedge” through periods of hostile conditions (low temperature, low light, poor resources or food availability, drought, and so on). The inocula potentially supplied by subsequent germination and egg hatching provide a powerful mechanism for maintaining diversity in seasonally fluctuating environments.

In many cases, the propagules facilitate spatial transfers as well. Dispersal in water droplets, or in dust, or in or on the bodies of animals have been shown to be effective pathways of planktonic organisms (review of Kristiansen, 1996) and to have been directly implicated in the establishment of populations in new or isolated bodies of water (Maguire, 1963, 1977). Planktonic species are not equally amenable to dispersal; for instance, effective perennation and dispersion are essential properties of species of temporary or temporally variable habitats. In general, invasiveness of propagules is dependent on a raft of species-specific features such as their sizes, their resistance to desiccation, and the numbers and frequencies with which they are produced. The probability (p) of a given species (A) being able to establish itself in another water body will be determined as a function, partly of its relevant species-specific traits (T_A) and partly of the problems posed to all would-be invaders of the distance (d) and size (a) of the new (or “target”) site from the existing (or “source” MacArthur and Wilson, 1967) population:

$$p = f(1/d, a, T_A)$$

An important converse of this relationship also manifests itself in relation to the ongoing suitability or effectiveness of

source and target sites as a habitat for the given species. Either because the habitat changes in consequence of autogenic properties or because species A is prevented from completing its perennation in that habitat, through the intervention of a facultative predator or pathogen, it is ultimately likely that the survival of the species in that location is at risk. Repeated at several sites, this process would threaten the survival of the species in its entirety and bring about a diminution in total species richness (i.e., the biodiversity). The resistance to that comes, quite literally, from the patch dynamics of habitat distribution and their temporal suitability to species A . Thus, the status of species A is a function of the number of possible habitat patches (N), the number that is occupied (O), the rate at which they become excluded there from (e), and the probability (p) of colonizing the ($N-O$) unoccupied habitats. The rate of expansion (or loss) of the metapopulation in time (dO/dt) may then be symbolized:

$$(dO/dt) = pO(N - O) - cO$$

For the more familiar and (supposedly) more cosmopolitan planktonic forms, relative ease of dispersal is, manifestly, the dominant factor upholding the widespread occupancy among suitable habitats. For the majority of known species that are relatively rare (that is, there is a relatively low occupancy among the total number of patches), effective dispersal may be resisted by specific traits (T_A) or simply by low numbers. In this case, survival may be considered more tenuous. However, from the limited investigative evidence available, many of these rarer species have been numerous in the past and occasionally continue to perform relatively well on the inertia of persistent, viable propagules. While the length of this “ecological memory” (Padišák, 1992; Padišák *et al.*, 2010) is not certainly quantified, we may be aware of the fact that it is generally the rarer species that contribute most to the total biodiversity of planktonic organisms. Although the metabolically significant planktonic biomass relies on the productivity of a relatively small number of species in a series of variable and renewable habitats, the majority of species is limited to habitats in which temporal variability is less extreme or exclusion is long protracted.

Conclusions and Implications

The feature distinguishing plankton-based ecosystems from terrestrial ones is that the relevant temporal scales are mostly much shorter in open waters than on the land. Not only are the mechanisms of planktonic biodiversity conveniently observed, but also the study of planktonic systems may be rewarded with insights into current issues about the importance and the protection of biodiversity.

Of the many propositions that have been advanced about the role of diversity in upholding ecosystem processes, current attention focuses mainly on four broad postulates (Lawton, 1997). In various ways, they relate to Darwin’s (1859) proposition that a large number of species imparts a higher level of functional stability than does a small one. Thus, to lose species inevitably impairs the functional integrity of the ecosystem. The “redundant species hypothesis” counters that, because

species are not equally represented, some are contributing much more than others to ecosystem function. Indeed, some “keystone species” (Paine, 1969) drive the main functions and have a much stronger influence than “passenger” species (Walker, 1992). Then, logic suggests, a minimal diversity is essential to adequate ecosystem functioning and most of the species are really redundant in their roles (Lawton and Brown, 1993; Walker, 1992). Almost diametrically opposed to this view is the “rivet hypothesis” (Ehrlich and Ehrlich, 1981), which accords to each species an essential contributory role, and which, if lost from the whole, like rivets lost from the structure of an aircraft, quickly leads to serious functional impairment and failure. A third hypothesis takes a much looser view, suggesting that function is modified by changes in the richness of species composition but in unpredictable ways (“idiosyncratic”; Lawton, 1994) because the contributions of individual species to system function are unequal. The fourth possibility is the null hypothesis that ecosystems are insensitive to changes in species composition. This seems increasingly to be implausible and will not be discussed.

One of the important lessons from the plankton scale is that a distinction should be made between structural stability and functional stability. Taking the basic function of the plankton to be the material cycling in open water, driven by solar energy invested in carbon bonds, the photoautotrophic, heterotrophic, and phagotrophic roles are fulfilled, respectively, by any or all of a large number of species of phytoplankton, bacterioplankton, and zooplankton. Despite having vastly different and frequently changing species compositions, studies of the productivity of planktonic systems demonstrate a remarkable level of functional coherence (Schindler, 1990). In this way, pelagic fish may continue to feed planktivorously and to respire photosynthetically generated oxygen almost without reference to the planktonic structure, as long as similar functions are maintained.

At the level of planktonic communities, a decline in the population of a dominant species will carry fewer implications if a second species is poised to substitute quickly. Frost *et al.* (1995) made the case that species complementarity is made for functional compensation of the smaller scales of structural variability. The case is analogous to the arguments about the flexibility of communicating information through networks rather than along a single pathway (Pahl-Wostl, 1990), or what has been called the “World Wide Web” explanation of biodiversity (Reynolds, 1997). This recognizes the idea that some species may contribute less to overall ecosystem function than other, more functionally creative keystone species (following Paine, 1969) or “ecosystem engineers” (Lawton, 1997), and providing opportunities to others may also serve to promote and maintain the species richness. It also values the role of the reserve (richness) of complementary species able to fulfill the compensatory function.

What clues does planktonic diversity give us about the approaches to uphold species richness in other ecosystems? The advice, “Keep up the disturbance,” is a little trite and somewhat counterintuitive to traditional conservation attitudes. Only at the global scale of aquatic systems is it possible to conceive the simultaneous existence of sufficient a range of habitats to accommodate the entirety of species. No single location, no matter how variable, offers habitat or refuge for

more than a minority representation of the aquatic biota. Aquatic biodiversity has to be pursued at the scale of fluvial catchments and regional seas – every lake, pond, evolving flood plain, river estuary, coastal shelf, and ocean circulation is but a piece in the biospheric mosaic. The essential general aim should be to ensure that suitable habitat elements persist, each in a range of developmental states. Local extinctions are resisted by good between-locality communication of propagules. In this sense, managing biodiversity has to adopt the philosophies of patch dynamics, taking full account of the longevities and the invasiveness of species-specific populations in relation to the externally influenced availability and renewal of suitable patches.

Glossary

Chromophore A part of a molecule that absorbs light.

Metagenomics Analysis of genomic deoxyribonucleic acid from complex environmental populations or communities (as opposed to specific cultured isolates) using molecular biology techniques. Keystone approach to determine the genetically encoded information of natural microbial populations and thereby of the great majority of microorganisms that cannot easily be cultured.

Photocycle In proteorhodopsin (PR), the photochemical reaction cycle (“photocycle”) denotes the process in which light energy absorbed by the retinal chromophore provokes a series of transient chemical changes in the PR molecule, which then returns to its dark state in times of less than 1 s.

This cyclic process results in the transport of a proton from the inside of the cell across the cell membrane.

Phototrophy In a wide sense, it signifies the capacity to obtain food or nutrition from light. In microbiology, it denotes the process whereby light is used as an energy source for metabolic processes. We currently know organisms that carry out oxygenic or anoxygenic photosynthesis using chlorophylls to harvest light, and organisms that contain microbial rhodopsins, which use retinal for the same purpose.

Retinal The rhodopsin chromophore, also called vitamin A aldehyde or retinaldehyde. Retinal is responsible for the color of rhodopsin pigments.

Proteorhodopsins (PRs) are microbial membrane proteins that use the retinal molecule (vitamin A aldehyde) as a chromophore and function as light-driven proton pumps (Béjà *et al.*, 2000a, 2001; Spudich and Jung, 2005). These microbial rhodopsins were first discovered in 2000 using metagenomic data from the uncultured SAR86 bacterial group, and their detection has been instrumental in the development of the metagenomics research field (Béjà, 2004; Kowalchuk *et al.*, 2007; O’Malley, 2007; Grote and O’Malley, 2011). Since their discovery in the SAR86 group, PRs have been detected in different abundant and cosmopolitan oceanic microbial groups belonging to Proteobacteria, Flavobacteria, Gram-positive bacteria, Cyanobacteria, Archaea, and even picoeukaryotes. Although most PRs have been identified in uncultured marine bacteria and archaea, the relative ease of working with PRs expressed in *Escherichia coli* bacteria has been central for dissecting their light-dependent proton pump activity (using advanced biophysical assays (Friedrich *et al.*, 2002; Wang *et al.*, 2003; Man-Aharonovich *et al.*, 2004; Sineshchekov and Spudich, 2004; Bergo *et al.*, 2009) and in suggesting a role in phototrophy (Martinez *et al.*, 2007; Walter *et al.*, 2007)). However, because all these works relied on the heterologous *E. coli* system, some concern has arisen regarding PR phototrophy relevance in the natural environments (Schwalbach *et al.*, 2005). Ecophysiological studies of native marine PR-containing bacteria are currently resolving these concerns (Gómez-Consarnau *et al.*, 2007, 2010; González *et al.*, 2008; Kimura *et al.*, 2011; Steindler *et al.*, 2011). PRs are estimated by different methods (metagenomics and real-time polymerase chain reaction (PCR)) to be found in approximately 10% (Sabehi *et al.*, 2005; Fuhrman *et al.*, 2008) and as much as 85% (Fuhrman *et al.*, 2008) of marine microbes in the photic zone. The fact that surface seawater holds nearly 1 billion microbes per liter thus implies that microbial PR

phototrophy directly influences oceanic energy and carbon fluxes.

PR Discovery and Mode of Phototrophy

The PR gene was discovered on a deoxyribonucleic acid (DNA) fragment belonging to a member of the uncultured bacterial SAR86 group isolated from Monterey Bay, CA, USA. This discovery became possible due to the development of methodologies to generate large-insert genomic libraries (bacterial artificial chromosome (BAC) libraries) of environmental DNA (Béjà *et al.*, 2000b). During analysis of the BAC libraries for genes involved in metabolism of particular members of the natural bacterioplankton community, the startling presence of the PR gene was noticed based on its weak homology (approximately 30% identity on the protein level) to haloarchaeal bacteriorhodopsins (Béjà *et al.*, 2000a; Figure 1). At the time of PR discovery, bacteriorhodopsins were already well characterized (Oesterhelt and Stoekenius, 1971; Danon and Stoekenius, 1974; Oesterhelt and Schuhmann, 1974), and their role as retinal-binding membrane proteins that function as proton pumps was well established (Lanyi, 1998; Haupts *et al.*, 1999; Spudich *et al.*, 2000). PRs were characterized first as proton pumps using heterologous expression in *E. coli*. *In vivo*, PR proteins fold correctly in *E. coli* membranes to form active colored proton pumps (Figure 2), an ability not shared by their well-characterized close relatives, bacteriorhodopsins. The first experiments were performed using retinal molecules added externally because *E. coli* does not possess the enzymatic capacity to synthesize retinal. In later experiments, *E. coli* was engineered to produce retinal via different operons found in different cultured and uncultured bacteria (Sabehi *et al.*, 2005; Kim *et al.*, 2008). Similar to

Figure 1 Schematic representation of a microbial rhodopsin tree. Modified from McCarren J and DeLong EF (2007) Proteorhodopsin photosystem gene clusters exhibit co-evolutionary trends and shared ancestry among diverse marine microbial phyla. *Environmental Microbiology* 9: 846–858.

Figure 2 Pigmented *E. coli* cells expressing different PR variants from the Red Sea. Modified from Man D, Wang W, Sabehi G, *et al.* (2003) Diversification and spectral tuning in marine proteorhodopsins. *EMBO Journal* 22: 1725–1731.

bacteriorhodopsins, PRs are believed to work using *all-trans*-retinal as chromophore. This expectation is mainly based on their high degree of conservation of retinal-binding pocket residues with other microbial rhodopsins, which use *all-trans*-retinal (Spudich *et al.*, 2000), the generation of photoactive functional pigments in *E. coli* membranes by exogenous *all-trans*-retinal (Béjà *et al.*, 2001), analysis of native planktonic

membrane preparations (Béjà *et al.*, 2001), and on analyses of known retinal biosynthetic operons identified in DNA fragments coming from uncultured bacteria containing PR genes (Sabehi *et al.*, 2005). However, it has not been ruled out that, in the environment, PRs may interact with other chromophores as well (e.g., 3-hydroxyretinal; Sabehi *et al.*, 2004).

Using the *E. coli* system, it is now well established that PRs are indeed retinal-based light-driven proton pumps (Béjà *et al.*, 2000a, 2001; Man-Aharonovich *et al.*, 2004; Sabehi *et al.*, 2005; Martinez *et al.*, 2007; Walter *et al.*, 2007; Kralj *et al.*, 2011). Furthermore, using the same system, it was demonstrated that the PR light-driven proton pumping is coupled to adenosine triphosphate (ATP) biosynthesis (Martinez *et al.*, 2007; see Figure 3 for a simple view of the process). Moreover, the PR proton pumping is also likely to provide the proton motive force to drive energy-requiring processes, such as flagellar motility or nutrient transport across the cell membrane.

Although the work with heterologous expression in *E. coli* enabled the biochemical and physiological characterization of the PR pump, establishing an authentic ecological role for the PRs has largely depended on the study of native bacteria containing PRs. The first ecophysiological experiments with marine bacteria containing PR was carried out with cultured members of the SAR11 group (Giovannoni *et al.*, 2005a) and the SAR92 group (Stingl *et al.*, 2007). SAR11 bacteria (Morris *et al.*, 2002). *Candidatus Pelagibacter ubique* (Rappé *et al.*, 2002) are abundant and cosmopolitan Alphaproteobacteria that contain PRs (Giovannoni *et al.*, 2005a, b). Notably, the first attempts to show light-stimulated growth in both SAR11 and

Figure 3 A simple view of a PR energy circuit. PR uses light energy to translocate protons across the cell membrane. The excess extracellular protons create a proton motive force, which can energetically drive flagellar motility, transport processes, or ATP synthesis in the cell. For the latter, a proton-translocating ATPase, a multiprotein membrane-bound complex, utilizes the proton motive force to synthesize ATP.

SAR92 failed (Giovannoni *et al.*, 2005a; Stingl *et al.*, 2007). This greatly heated up the discussion over the true relevance of PRs in the environment (Giovannoni *et al.*, 2005b; Schwabach *et al.*, 2005; Bryant and Frigaard, 2006; Fuhrman *et al.*, 2008; Miyake and Stingl, 2011).

Light-stimulated growth mediated by PR phototrophy, coupled with biophysical characterizations of the PR molecule, was first observed in a series of experiments with a PR-containing marine Flavobacteria, *Dokdonia* sp. strain MED134 (Gómez-Consarnau *et al.*, 2007). Subsequent independent experiments with the same strain recently confirmed these observations and further showed that inhibition of retinal biosynthesis in strain MED134 abolished the light response, supporting a direct role for PR in stimulating growth in the light (Kimura *et al.*, 2011). In another PR-containing Flavobacteria, *Polaribacter* sp. strain MED152, experiments indicate that the energy provided by PR phototrophy could be used to fuel CO₂ fixation (González *et al.*, 2008). Direct evidence for the role of PR phototrophy in a marine bacterium first came with the mutational analysis of the PR gene in *Vibrio* sp. AND4 (Gómez-Consarnau *et al.*, 2010), where it was also shown that the energy provided through PR promotes survival during extended starvation conditions. In a similar manner, although

initially no effect of light was seen during growth in members of the SAR11 group, ATP production through PR phototrophy was recently shown to be beneficial for SAR11 during starvation (Steindler *et al.*, 2011). Collectively, these experimental results from native marine bacteria strongly substantiate the original suggestion that phototrophy mediated by PR may influence global oceanic carbon and energy fluxes (Béjà *et al.*, 2000a).

PR Abundance and Diversity

The uncultured gammaproteobacterial group SAR86 in which PRs were first detected is widespread in different oceanic regions (Eilers *et al.*, 2000; Suzuki *et al.*, 2001). PRs are also found in the cosmopolitan alphaproteobacterial SAR11 group (Giovannoni *et al.*, 2005a; Steindler *et al.*, 2011) and in the SAR116 group (Oh *et al.*, 2010). These three bacterial groups alone comprise as much as 70% of the bacterial community in most surface waters around the world. PRs are also readily detected in other microbial groups, including other Alphaproteobacteria (see table in DeLong and Béjà, 2011); Betaproteobacteria (Giovannoni *et al.*, 2008); Gammaproteobacteria (Gómez-Consarnau *et al.*, 2010); Flavobacteria (Gómez-Consarnau *et al.*, 2007; González *et al.*, 2008); Planctomycetes (McCarren and DeLong, 2007); Cyanobacteria; Actinobacteria (Sharma *et al.*, 2008, 2009); marine Archaea (Frigaard *et al.*, 2006); and different eukaryotic groups, including fungi (Spudich and Jung, 2005) and dinoflagellates (Okamoto and Hastings, 2003; Slamovits *et al.*, 2011). The widespread distribution of different PRs in different microbial groups could be explained by frequent horizontal gene transfer of the PR gene (Frigaard *et al.*, 2006) and the adjacent retinal biosynthetic operon (McCarren and DeLong, 2007).

PRs have been reported in a variety of aquatic habitats, including the marine environment (Béjà *et al.*, 2000a, 2001; de la Torre *et al.*, 2003; Balashov *et al.*, 2005; Giovannoni *et al.*, 2005a; Sabehi *et al.*, 2005; Frigaard *et al.*, 2006; Gómez-Consarnau *et al.*, 2007, 2010; Campbell *et al.*, 2008; Cottrell and Kirchman, 2009; Lami *et al.*, 2009; Oh *et al.*, 2010), sea ice (Koh *et al.*, 2010), brackish environments (Rusch *et al.*, 2007; Atamna-Ismaeel *et al.*, 2008), and freshwater lakes (Atamna-Ismaeel *et al.*, 2008; Sharma *et al.*, 2008, 2009). Recently, PRs have also been detected on leaf surfaces of plants, i.e., phyllospheres (Atamna-Ismaeel *et al.*, 2012). Leaf surfaces of terrestrial plants cover an estimated surface area of 6.4×10^8 km² and comprise the main interface between terrestrial biomass and solar photon flux. This habitat harbors an immensely diverse microbial community of as much as 10^6 – 10^7 cells per cm² leaf surface (Lindow and Brandl, 2003). A mode of phototrophy that is compatible with the plant's photosynthesis would offer a significant ecological advantage to microbes inhabiting this environment.

PR genes have been found in different environmental genomic studies on large environmental DNA fragments and in different metagenomics studies that use different sequencing techniques and also using single-cell genomics (Stepanaukas and Sieracki, 2007; Woyke *et al.*, 2009; Martinez-Garcia *et al.*, 2011). In addition to the detection of specific genes, PRs have been detected in different metatranscriptomics studies and in

high numbers (Frias-Lopez *et al.*, 2008; Poretsky *et al.*, 2009; Shi *et al.*, 2010). In addition, PRs were also detected as proteins (peptides) in different environmental metaproteomics studies (Giovannoni *et al.*, 2005a; Morris *et al.*, 2010), and their proton-pumping photocycles detected spectroscopically in ocean plankton (Béjà *et al.*, 2001). Taken together, the results from studies with PRs on the DNA, ribonucleic acid, and protein levels confirm the importance of this photoprotein in light-exposed environments.

PR Spectral Tuning

PR spectral tuning was first observed among genes amplified directly from the environment by using highly specific PCR primers (Béjà *et al.*, 2001) to PRs from the SAR86 group. These genes produced pigments of two distinct absorption spectra – “green-absorbing” and “blue-absorbing” PR types – which shared >78% of their amino acid residues. Moreover, a single residue change at position 105 (leucine for green PRs and glutamine for blue PRs) functions as a spectral tuning switch to account for most of the spectral difference (Man *et al.*, 2003). In fact, the switch of a single residue from leucine to glutamine in PRs requires a switch of only one nucleotide (a change of a CTA or a CTG codon to a CAA or CAG codon, respectively). Initial work performed in the Pacific Ocean (Béjà *et al.*, 2001) identified green PRs mostly in shallow water, whereas blue PRs were identified in deeper waters (below 70 m). A similar trend was also observed in the Mediterranean Sea. However, in the Sargasso Sea, despite the green light available at the surface, blue PRs were observed on the surface and green PRs were almost absent.

Future Exploration

Antenna-assisted PRs

More recently, a new type of microbial rhodopsin was found: xanthorhodopsin (Balashov *et al.*, 2005). Xanthorhodopsin is a light-driven retinylidene proton pump complexed with a carotenoid molecule, salinixanthin, which functions as a light-harvesting antenna and transfers energy to the rhodopsin protein (Lanyi and Balashov, 2008). It was recently suggested that the ability of rhodopsins to bind salinixanthin depends on a single glycine residue (Imasheva *et al.*, 2009). It was recently suggested (DeLong and Béjà, 2011) that a number of PRs could potentially bind carotenoid antennae because some environmental PRs carry the homologous glycine residue in the correct position. Such a complex would mean that PRs in nature would be able to harvest a larger part of the light spectrum and would not be restricted to blue or green light.

Photoreactions and Mechanism

Light absorbed by the retinal chromophore in PR initiates a series of transient chemical changes in the molecule, which then returns to its dark state in times of less than 1 s. This cyclic process, called a photochemical reaction cycle (“photocycle” for short), results in transport of a proton across the

membrane. Key events in the PR photocycle are the transfer of a proton from the chromophore site to a negatively charged aspartate in communication with the outside environment, followed by a conformational change that switches the accessibility of the chromophore site to the cytoplasmic side of the protein, and then transfer of the proton from a neutral glutamate residue on the cytoplasmic side to the chromophore site (Dioumaev *et al.*, 2002). These proton transfers are homologous to those occurring in bacteriorhodopsin (Lanyi, 1998), but other residues involved in proton transport in bacteriorhodopsin, including an important proton release group, are not conserved in PR. Many aspects of the PR-pumping mechanism remain unresolved, and an important goal for the future is to obtain an atomic resolution structure of PR to enable its molecular mechanism to be elucidated.

Comparison of ocean sequences shows the presence of the aspartate proton acceptor and glutamic acid proton donor residues in 97% of the PR-encoding genes, consistent with their expected proton-pumping function. However, the remaining 3% lack the proton donor residue, which is characteristic of microbial sensory rhodopsins rather than proton pumps. Further evidence from adjacent genes provides strong support for the existence of “sensory PRs” in the ocean (Spudich, 2006). In the recent report of PRs in phyllospheres, the percentage of putative sensory PRs was found to be much larger (25–70%). Compared with marine bacteria, phyllosphere microbes may have a greater need for light sensing than energy capture by microbial rhodopsins because the leaf surface is rich in nutrients but adaptations are needed to counteract the effects of fluctuations in light quality, intensity, and ultraviolet radiation (Atamna-Ismaeel *et al.*, 2012). The physiological functions of the sensory PRs are an interesting mystery for future exploration.

Glossary

Benthos The substrate at the bottom of the sea or fresh waters. Most benthic protozoa live in the spaces between sediment particles.

Commensal Of a protozoon – one that is loosely but not obligately associated with another organism (e.g., the ciliates attached to the external surfaces of crustacean zooplankton).

Endosymbiont An organism living in a long-term association inside a host organism for their mutual benefit (e.g., the endosymbiotic methanogenic bacteria that live

inside anaerobic protozoa and utilize waste H₂ produced by the host).

Eukaryote An organism with membrane-bounded nuclei in its cells. Protozoa are unicellular eukaryotes.

Heterotrophic Mode of nutrition in which carbon is obtained from the organic compounds made by autotrophic organisms.

Phagotroph An organism that ingests solid food particles (e.g., bacteria).

Planktonic Living in the water column of lakes or the sea.

Protozoa are microscopic organisms with animal-like features. Each protozoon typically exists as a single, independent cell, and all free-living protozoa fit to the definition of phagotrophic microbial eukaryotes. In some species, independent cells unite to form colonies (e.g., colonial choanoflagellates) (Lee *et al.*, 2000). There has never been unanimous agreement as to where the boundaries of the protozoa should lie, largely because of the extraordinary diversity of their lifestyles (Margulis *et al.*, 1990). Many species cause disease (e.g., malaria): Others thrive as commensals in the digestive tracts of ruminants and wood-eating insects, and many plant-like flagellates (e.g., *Euglena*) have at various times been referred to as protozoa, algae, or plants. Here, the authors are concerned principally with free-living protozoa, and the definition of this group is not taxonomic but one that is based on its key function in the natural environment: Protozoa are capable of phagotrophy – the ability to capture and ingest food particles (Fenchel, 1987). Many also have functional chloroplasts or endosymbiotic algae, and the resulting consortia are known as “mixotrophs” because they are capable of both phagotrophy and phototrophy (Esteban *et al.*, 2010). Like most microorganisms, protozoa have very large population sizes, and they are the most abundant group of phagotrophic organisms in the biosphere. Biodiversity at the level of protozoa has characteristics that are not shared by macroscopic animals and plants. Most protozoan species are probably globally ubiquitous, so the global number of species is relatively small. A significant proportion of local protozoan species richness, at any moment in time, is rare or cryptic and awaiting the arrival of environmental conditions suitable for growth and reproduction.

Functional Roles

All of the important functional roles of free-living protozoa derive from their small size. The smallest flagellates are

2–4 µm and most are <20 µm, most amebae are <50 µm, and most ciliates are <200 µm. Exceptionally, some ameboid protozoa, such as the radiolarians and foraminiferans, and the agglutinated foraminiferans of the deep-sea benthos, may reach 2 mm or more, especially if they have spiny extensions. Because protozoa are so small, most suitable prey items are other, smaller microbes. Protozoa are the principal consumers of the immense natural resource of bacteria and other microorganisms, and because they have population growth rates that are similar to those of the microbes on which they feed (doubling times on the order of one to several days), they are usually able to control microbial abundance. Flagellated protozoa can probably consume all bacterial production in the plankton. In the benthos, protozoa overlap in their niche requirements with nematodes, rotifers, tardigrades, turbellarians, and gastrotrichs, but because of their great abundance protozoa are indeed quantitatively the most important grazers in the freshwater and marine (including deep-sea) benthos. Also, just as microbes achieve astronomical abundance on a global scale, so too are the protozoa that graze on them represented by species populations with proportionately smaller but still unimaginably large global abundances.

Protozoan grazing on microorganisms also stimulates activity of the whole microbial community, in both oxic and anoxic environments. The process involved is not fully understood, although it may operate by increasing the rate of turnover of essential nutrients that would otherwise remain locked up in the bacterial biomass. The net effect is that grazing by protozoa stimulates the rate of decomposition of organic matter (Fenchel, 1985; Finlay *et al.*, 1997).

The variety of shapes, sizes, and relative abundances of microbial food items has driven the evolution of a comprehensive suite of methods to capture them and a considerable diversification of protozoan morphologies. In general, the size of a protozoon relative to its prey dictates the most efficient food-capturing mechanism. Where the predator is

typically much larger than its prey, filter-feeding prevails, and where the size difference is less the protozoon is more likely to be a raptorial feeder – one that seeks out relatively large individual food items. Thus, the planktonic choanoflagellate feeding on a dilute suspension of tiny bacteria 20 times smaller than itself does so with a very fine filter, and the ciliate feeding on dinoflagellates half of its size seeks out and captures each one individually. There are, of course, many exceptions, such as the marine heterotrophic dinoflagellates that use a feeding veil to trap and digest diatoms much larger than themselves.

The third main feeding type in protozoa is termed “diffusion feeding.” This is particularly common in planktonic ameboid protozoa (radiolarians, foraminiferans, and heliozoans) and in the suctorians ciliates. It works when prey items collide with the sticky spines, tentacles, or axopods that radiate from the protozoon. Unlike the other two main modes of feeding, the protozoon simply waits for the arrival of its prey, much as a spider waits for an insect to be snared in its web.

Thus, there is a close link between protozoan morphology (especially of the food-capturing organelles) and the way in which a protozoon functions as a grazer. Therefore, when the authors classify the free-living protozoa into broad morphological groups, they are simultaneously allocated to broad functional groups. The three broadest morphological–functional groups are the ameboid, the flagellated, and the ciliated protozoa, and each has its own strengths as a phagotroph. Representatives of all three may feed on the same type of microbes in the same place (e.g., in an aquatic sediment), but they will differ in the mechanics and efficiency of capture of any particular food particle. A filter-feeding flagellate will have a relatively large filter area, a high volume-specific clearance and competitive superiority over filter-feeding ciliates when grazing on planktonic bacteria. A helioflagellate and a suctorian ciliate will both practice diffusion feeding, but the former will be adapted for snaring bacteria, whereas a diffusion-feeding suctorian will specialize in trapping flagellates and ciliates.

Many protozoa are microaerophilic: They seek out habitats with a low level of dissolved oxygen that is just sufficient to drive their aerobic respiration and low enough to exclude metazoan competitors and predators. Microaerobic habitats are common in aquatic sediments and in oceanic oxygen minimum zones. These are zones in which the raw materials for microbial growth arrive from opposite directions (e.g., where oxygen and light arriving from above meet carbon dioxide and sulfide from below) and in which there is therefore an elevated abundance of microbial food. Therefore, microaerophily is an adaptive behavior: It brings protozoa into contact with high abundances of microbial food. It also stimulates the growth of nutritional symbionts such as sulfide-oxidizing bacteria and endosymbiotic algae. Many microaerophilic protozoa are also temporary anaerobes, but unlike the true anaerobes that live permanently in the absence of oxygen, their metabolism is fundamentally aerobic. The true anaerobes – those that complete their entire life cycle in the absence of oxygen – live principally in aquatic sediments. There are many species, but none is ever abundant. Most use hydrogen-evolving fermentations for energy generation, and the hydrogen is used by anaerobic bacteria, especially endosymbiotic methanogens. Thus, methane is released from these

protozoan consortia. The anaerobic protozoa are probably the only phagotrophic organisms capable of living permanently in the absence of dissolved oxygen (Fenchel and Finlay, 1995).

The real diversity of symbiotic associations involving protozoa is poorly known. In some cases, complex interactive behaviors have evolved between the partners. In the marine, sand-dwelling ciliate *Kentrophoros*, the entire dorsal surface of the ciliate is a coat of sulfide-oxidizing bacteria that can grow only in the narrow layer within the sediment where oxygen and sulfide overlap. The ciliate host’s innate microaerobic behavior enables it to seek out the habitat that the symbiotic bacteria need for growth. The ciliate then invaginates its dorsal surface and digests the bacteria because it does not have a mouth, and this is its only source of nutrition.

It is clear that many of these symbiotic consortia involving protozoa represent tightly integrated functional units; indeed, the symbionts may be almost as deeply embedded functionally in the consortium as the protozoon’s other organelles. Two points must be noted. First, it is the combined phenotype of the consortium, rather than that of any individual consortium partners, on which natural selection will operate, and there are examples of how the fitness of a protozoon in a particular habitat can be improved by the acquisition of endosymbionts (e.g., the algal symbionts of ciliates living in the metalimnia of freshwater lakes). Second, the biodiversity of protozoa, when quantified simply in terms of protozoan species richness, will fail to take account of the large supplementary microbial diversity with which the protozoa are necessarily associated.

Therefore, the diversity of free-living protozoa may be classified into broad morphological–functional groups: ameboid, flagellated, and ciliated protozoa. Almost any free-living protozoon can be placed without difficulty in one of these groups. It must be stressed, however, that these groups are not concordant with any system of classification of protozoa published in recent years; nor are they in most cases aligned with the independent lineages that are emerging in the molecular phylogenies (e.g., those based on sequence variation in ribosomal RNAs) which reflect the main episodes in the history of eukaryotic evolution. Heterotrophic flagellate groups, such as the diplomonads and trichomonads, appear in the early emerging lineages, but other flagellates (e.g., choanoflagellates, chrysomonads, dinoflagellates, and haptomonads) are classified within recently diverging lineages. The ameboid protozoa too are scattered across many lineages. The naked amebae without mitochondria (the pelobionts) diverge early and close to the diplomonads, whereas the vahlkampfiids, slime molds, and various other groups of naked and testate amebae appear in other independent lineages that are evolutionarily quite distant from each other. The morphological–functional group of the ciliates is the only one which remains intact, as a monophyletic group, in current molecular phylogenies.

The process of distilling the vast quantity of molecular information generated in recent years has generated some entirely new phyletic assemblages, including the stramenopiles, a group containing organisms as morphologically and functionally dissimilar as chrysomonad flagellates and diatoms, and the alveolates – a group that embraces the dinoflagellates, the ciliates, and a large group of exclusively intracellular parasites

(the apicomplexans) (Adl *et al.*, 2005). In the next section, the authors focus on the broad morphological–functional groups of free-living protozoa, define what is meant by species, and quantify the species within these groups.

The Nature of Protozoan Species

There is no universal agreement on what constitutes a protozoan species. The most widely used concept is the morphospecies because it is relatively easy to discriminate a great diversity of protozoa using body form alone. This concept is especially useful because morphology is closely related to the ecological function. In many free-living protozoa, the structure of the feeding apparatus and the size and shape of the cell determine how the protozoon functions in the natural environment; therefore, the cell form largely determines the ecological niche that the protozoon occupies. Discriminating species on the basis of form might then be equivalent to discriminating them according to the ecological niches they occupy. We could say that if a protozoon looks the same in different places, then it is the same in different places. However, there are problems with such a simple concept. It is known that a morphospecies can be composed of ecologically distinct populations, such as those adapted for maximum growth rate at different temperatures. Therefore, although it is possible to collect apparently identical representatives of a morphospecies in different corners of the world, and one might be encouraged by the belief that they were filling exactly the same niche in these different places, in reality they could be phenotypically quite different. The same problem applies with respect to genetic differences. It is possible to find genetic differences, especially sequence differences in ribosomal RNAs, in morphologically identical isolates collected from different places. The significance of these genetic differences is not known; nor is it known if genetic and phenotypic divergence are correlated. It appears, however, that there is no correlation between genetic divergence and geographic distance.

Protozoa spend most of their time as asexual organisms, but some do reproduce sexually, if only periodically, and in some well-studied cases (e.g., the ciliate genera *Tetrahymena* and *Paramecium*) morphologically indistinguishable biological species (reproductively isolated gene pools, also known as sibling species) have been studied thoroughly. Different sibling species within a morphospecies may be genetically identical to each other or extremely divergent (at least with respect to ribosomal RNAs), and there is no apparent correlation between genetic isolation and genetic divergence. Again, there is no good evidence for biogeography of protozoan sibling species, and members of the same sibling species can be found on different continents. It is possible that sibling species carry unique phenotypic traits that equip each species for a particular niche, but this has not been demonstrated. The real problem in using a biological species concept for protozoa is that it is not practical for all but a few easily cultivated protozoa. The majority of protozoan species have never been cultivated, and neither the frequency nor the character of their sexual behavior (if any) are known or are ever likely to be known. Most people who study protozoa in the natural

environment use the morphospecies concept because it is practical, it embodies the close link between form and function, and it is the morphospecies that fills the niche, if not always the minutest niches, that can be discerned by the human observer. The morphospecies may contain much genetic variation and be capable of expressing a wealth of phenotypic variation, but it is the best tool that is available for ordering the diversity that lies within the protozoa.

One particular problem that is particularly acute when dealing with organisms the size of protozoa is that the quality of one's perception of morphology is very definitely a function of the tools that are available (Mitchell and Meisterfeld, 2005). Thus, better tools (e.g., quality microscopes) enable the discrimination of finer detail. The logical extension of this is that even individual protozoa in a population might be discriminated one from the other and could therefore be referred to as separate morphospecies. Modern optics have undoubtedly lent impetus to the business of describing many new species, some of which are undoubtedly legitimate, whereas many have been established on morphological criteria that are trivial or have no conceivable functional significance.

An additional problem with the morphospecies is that it is often difficult to decide exactly where a species begins and ends. Although most observations are made of the vast number of individuals that cluster around the central tendency of any population, the individuals at the tail ends of the distributions abut and often overlap those of other species. Morphological variation then appears to be continuous across many species. Examples of this have been described: In some of the large spongiöse spumellarian radiolarians, the major features (e.g., skeletal and cytoplasmic morphology) that are used to discriminate species intergrade to such an extent that it is not possible to unambiguously ascribe individual radiolarians to nominal species.

However, the evolutionary process in radiolarians and other protozoa probably works in the same way as it does for other organisms such that it maintains phenotypically discrete species in niche space that is essentially continuously variable. The phenotypic traits that sustain these discrete species in protozoa are presumably quite diverse in character and possibly not totally comprehensible. Among the more accessible of these traits are the morphological characters that the authors use to separate species. However, the likely limitation of these is that they enable us to perceive only the fairly coarsely resolved, sometimes overlapping entities that we call morphospecies.

Protozoa and Ecosystem Function

Protozoa are abundant. One gram of soil typically contains 103–107 naked amebae, 105 planktonic foraminiferans can often exist beneath 1 m² of oceanic water, and almost every milliliter of fresh water or sea-water on the planet supports at least 100 heterotrophic flagellates. When expressed in global terms, these numbers are very large, and an inevitable consequence of the persistence of such a large number of very small organisms is that migration rates will be relatively high. It follows that rates of speciation and extinction must be low,

as will the consequent global number of species. It also follows that protozoa are unlikely to have biogeographies, and endemic species probably do not exist. The authors might expect that the local diversity of protozoa would account for a significant proportion of global diversity, even if at any moment in time much of this diversity is represented by rare or inactive individuals (e.g., cysts awaiting the arrival of suitable conditions). There is indeed good evidence for the global distribution of protozoan species, including the morphologically distinctive flagellate *Rhynchomonas nasuta* that has been found in most aquatic and terrestrial environments worldwide; marine foraminiferans and ciliates found living in slightly salty water of desert oases, hundreds of kilometers from marine coasts; the same radiolarian species living in high northern and southern oceanic latitudes; the same pond-dwelling ciliates living in Australia and northern Europe; and the cosmopolitan distribution of the same species of agglutinated foraminiferans in the deep-sea benthos. In general, protozoan morphospecies are ubiquitous and apparently cosmopolitan if the habitats to which they are adapted are distributed in different parts of the world (Finlay, 1998, 2002). In accordance with this, the global number of protozoan species is indeed relatively modest (Table 1), and the number of species that can be retrieved from a local area (e.g., a pond), in both active form and from a passive state is a significant proportion (usually at least 10% for various morphological-functional groups) of the global total. This fact may not be obvious from short-term ecological sampling programs because only a limited number of microbial niches are available at any moment in time.

Protozoa and other microorganisms have other special properties. Microbial activities interact strongly with physical and chemical factors in the natural aquatic environment (e.g., light transmission or the concentrations of essential nutrients) to create a continuous turnover of microbial niches. These niches are quickly filled from the locally available diversity of rare and dormant microbes, and the activities of the latter create further reciprocal interactions. Therefore, the diversity of active protozoan species in a pond, at any moment in time, is the result of preceding reciprocal interactions involving many biological and nonbiological factors, and the biodiversity of protozoa and other microbes is an integral part of ecosystem functions such as carbon fixation and nutrient cycling (Finlay *et al.*, 1997).

Biological Diversity and Global Species Richness

Ameboid Protozoa

Slime molds may be regarded as protozoa because they spend most of their active lives as amebae or as naked ameboid (and often macroscopic) plasmodia (Figure 1). They have been known by many names, including mycetozoa (fungus animals), because although they never develop hyphae they produce fruiting bodies (sporangia) supported on cellulose-rich stalks. There are two large groups – the cellular slime molds (the dictyostelids, e.g., *Dictyostelium*) and the acellular slime molds (myxomycetes, e.g., *Physarum*). Two smaller groups are the acrasids (e.g., *Acrasis*) and the protostelids

Table 1 Estimates of global species richness of extant free-living protozoa^a

			Marine	Nonmarine	Total
Ameboid protozoa	Slime molds	Dictyostelids	–	60	60
		Myxomycetes	–	550	550
	Rhizopod amebae	Naked	180	220	400
		Testate	–	200	200
	Foraminiferans	Planktonic	40	–	40
		Benthic, inshore	4000 ^b	–	4000
		Benthic, deep sea	250 ^b	–	250
	Actinopod amebae	Acantharians	150	–	150
		Radiolarians, solitary	750	–	750
		Radiolarians, colonial	50	–	50
Heliozonas		–	120	120	
Flagellated protozoa	Excluding heterotrophic dinoflagellates ^c	Marine plankton	420	–	420
		Marine benthos	330	–	330
		Freshwater and soil	–	350	350
	Heterotrophic dinoflagellates	900	110	1010 ^d	
	Other mixotrophic flagellates	–	–	150 ^e	
Ciliated protozoa		1400	1660	3060	
Total				11890	

^aCompiled from numerous published and unpublished sources. The more problematic estimates are highlighted.

^bThere is considerable uncertainty attached to these estimates. The figure of 4000 is generally accepted as a working figure for extant species but is probably inflated by synonyms, especially those of shallow-water benthic species. There is no firm information for species richness of deep-sea benthic foraminiferans (Gooday *et al.*, 1998). The estimate of 250 is approximately double the typical figure for local richness of species, most of which may be cosmopolitan, but there are probably many undescribed deep-sea soft-shelled foraminiferans that have in the past been ignored by geologists.

^cThe total given here for heterotrophic flagellates is 1100 species. This includes some synonyms and mixotrophs. It is believed by some that the real global total is closer to 3000 species.

^dAssuming there are 1800 marine and 220 freshwater species, and that 50% of these are heterotrophs.

^eThis estimate is simply derived by doubling some recent estimates. Note that these species may be only temporarily phagotrophic.

Figure 1 A selection from the variety of form and function in ameboid protozoa and slime molds. (1) an actinophryid heliozoon (*Actinophrys*; diameter of about 0.1 mm) ingesting a flagellate; (2) a benthic foraminiferan (*Rotalia*) trapping diatoms and bacteria in its reticulopodial net; (3) a naked amoeba (*Amoeba*) using pseudopodia to trap a flagellate; (4) a polycystine radiolarian (*Heliosphaera*; spherical body ~0.3 mm) with symbiotic dinoflagellates and an entrapped tintinnid ciliate; (5) polymorphic life cycles of dictyostelid slime molds (e.g., *Polysphondylium*; outer circle) and myxomycete slime molds (e.g., *Physarum*; inner circle); (6) testate amoeba (*Assulina*; ~0.08 mm) with its prey (an algal cell) caught on a sticky filopod.

(e.g., *Cavostelium*). The dictyostelids are typically phagotrophic amoebae, but when starved they aggregate, form a migrating slug, and then produce a fruiting body from which spores are released. These later germinate to produce amoebae. In the myxomycetes, individual amoebae (sometimes thousands of them) with or without flagella coalesce to form a distinctive (often brightly colored) multinucleate plasmodium which gives rise to fruiting bodies. Slime molds are common in damp forest soils, tree bark, and dead or dying wood, and abundance and local species richness are greater in deciduous than in coniferous forests. There is extreme patchiness in the distribution of dictyostelid species in forest soils, and co-existence of multiple species in the same small soil samples is

rare. Most myxomycete species are believed to be cosmopolitan. The phagotrophic amoeboid stages of slime molds may be quantitatively important grazers of bacteria, fungi, and the other primary decomposers of organic matter in soil. Other ecological interactions of slime molds may be at least as complex as their life cycles (e.g., the migrating slugs of dictyostelids appear capable of repelling grazing nematodes).

Rhizopod amoebae use pseudopodia for locomotion and feeding. There are two large groups (Figure 1) – the “naked amoebae” (e.g., *Acanthamoeba*, *Vannella*, *Amoeba*, and *Vampyrella*) and the shelled “testate amoebae” (e.g., *Arcella*, *Nebela*, and *Euglypha*). Most rhizopod amoebae feed nonselectively by engulfing diatoms and other algae, unicellular and filamentous

cyanobacteria, detritus, and bacteria. However, there are notable variants: *Vampyrella* dissolves a hole in the cell wall of a green alga or desmid and then enters through the hole to digest the cytoplasm of the prey. Some are opportunistic pathogens of man (e.g., in the genera *Acanthamoeba* and *Naegleria*).

Naked amebae occur in the plankton, but these species are usually very small ($< 10 \mu\text{m}$) and typically associated with suspended flocs (e.g., marine snow). However, it is likely that all rhizopod amebae need to be attached to a surface if they are to feed, and much larger numbers are found in aquatic sediments. Amebae are particularly abundant in soils (103–107 per gram dry weight), where together with heterotrophic flagellates they probably control bacterial abundance. A few testate amebae can be planktonic (e.g., *Diffugia*), but most live in soils and in *Sphagnum* bogs. The prey size of testates must be limited by the shell aperture size.

Naked and testate amebae offer different challenges when attempting to identify species. The naked forms are distinguished by the forms of their bodies and pseudopods in locomotion, but many species constantly change shape and the absence of fixed characters often makes it difficult to identify them without resorting to an analysis of ultrastructure. The testates construct tests which have species-specific architectures, but these are often modified according to the nutritional status and local environmental factors, such that the variety of tests described is extraordinarily large and the task of deciding where one nominal species begins and the other ends is at least as difficult as it is for the naked amebae. One practical solution to the problem of identifying living naked amebae in natural samples is to allocate them to one of the several broad morphotypes, e.g., those that extend lobose pseudopodia, slug-like forms with eruptive or noneruptive locomotion, and fan-shaped forms. No clear relationship has been established between morphology and ecological function in naked amebae, although it is likely that the limax (slug-like) amebae are predominantly benthic species.

Some naked amebae (especially those that form extensive anastomosing plasmodial networks) resemble hybrids of shell-free foraminiferans and slime molds. Some can reach several centimeters in diameter. They are typically very slow moving and apparently perfectly adapted for grazing extensive areas of soil surface (*Leptomyxa*) or diatom mats in the marine benthos (*Corallomyxa*). Some free-living naked amebae are anaerobic and do not have mitochondria. As a group, these are referred to as pelobionts, rhizomastigids, archamebae, or karyoblasteans (e.g., *Mastigamoeba*, *Mastigella*, and *Pelomyxa*). They are relatively common in organically enriched anoxic freshwater and marine sediments. The very large (up to several millimeters in diameter) *Pelomyxa* supports several types of endosymbiotic bacteria, including methanogens, and probably lives exclusively in freshwater sediments. It appears to ingest any organic particles with which it makes contact. It can be locally abundant and the dominant grazer in some anaerobic lake sediments. Most species of naked amebae have been described from fresh waters and soil, and most marine species have been collected from the inshore areas. It is not clear to what extent freshwater species can also live in seawater. Some genera (e.g., *Mayorella* and *Acanthamoeba*) are well represented in both environments.

Foraminiferans live in marine or brackish water environments, and most have calcareous shells (Figure 1). Cytoplasm emerges through the aperture and pores in the shell to form a repeatedly branching and anastomosing reticulopodial net in which prey are trapped (Lee et al., 2000). The spinose planktonic species (e.g., *Globigerinoides ruber*) have calcareous spines, and familiar Cretaceous chalk deposits (e.g., the white cliffs of Dover, UK) consist largely of the sedimented shells of these species together with the coccoliths of haptomonad flagellates. Some naked amebae that produce similar pseudopodial networks live in fresh waters (e.g., *Biomyxa*) or soil (e.g., *Reticulomyxa*).

The shells of planktonic foraminiferans are generally 0.1–1 mm in diameter, but the pseudopodial network can reach 10 mm and the spines may increase the size to more than 20 mm, making them larger than many marine metazoans. Planktonic species are open-water organisms. They are most abundant in tropical and subtropical waters, in which there is typically one per liter (or $\sim 10 \text{ m}^{-2}$, depth integrated to 150 m). Each species tolerates only small variations in temperature and salinity, and distinct assemblages of species are associated with five biogeographical provinces – the surface water masses of equivalent temperature on either side of the equator (polar, subpolar, temperate, subtropical, and tropical). However, species in these assemblages are not isolated from each other: Polar species have been recorded in upwelling zones at 10°N , and species characteristic of high latitudes are also found in the tropics, but in very deep and cool waters.

A typical planktonic foraminiferan produces a mass of reticulopodia (the “halo”) that radiates outward from the shell. This is used to snare prey and to support algal symbionts. Spinose species appear to prefer zooplankton prey, and nonspinose species (e.g., *Globorotalia menardii*) prefer phytoplankton. These preferences may affect the local distribution of species: In the Red Sea north of 20°N , the dominating spinose species appear to reflect the greater local abundance of zooplankton.

Many planktonic foraminiferans, especially the spinose species (e.g., *G. ruber*), contain algal symbionts that are carried along the spines by cytoplasmic streaming. There are probably only two types of symbionts in planktonic species: the dinoflagellate *Gymnodinium beii*, which is morphologically identical in many host species, and a small yellow-green (chrysomonad-like) symbiont. The symbionts are protected from digestion by the host. The carnivorous foraminiferan *Hastigerina pelagica* envelopes itself in a cytoplasmic bubble capsule which is probably a flotation device but is also used for trapping and digesting prey. *H. pelagica* does not have symbionts but commensal dino flagellates (*Pyrocystis* spp.) that live in the capsule. The role of symbionts and commensals is unclear. High rates of photosynthesis are maintained within the consortium, the symbionts probably transfer significant amounts of fixed carbon to the host, their photosynthetic activity may be necessary for calcification of the host’s shell, and the symbionts may use the host’s (nitrogenous) waste.

Benthic foraminifera have a greater diversity of symbiotic partners, including diatoms (*Nitzschia*), dinoflagellates (*Symbiodinium microadriaticum*), red algae, and chlorophytes (*Chlamydomonas*). Some also sequester chloroplasts from

ingested algae. Although many benthic foraminiferan species have been described, information on their life cycles and ecology is available for only about 20 shallow-water species (e.g., *Allogromia*, *Rosalina*, *Spiroloculina*, and *Sorites*). These typically drag themselves slowly over surfaces, continually extending reticulopodia to trap prey (diatoms, algae, and bacteria). The abundance of benthic species is correlated with local biological productivity. In the fertile Mississippi Delta, numbers may reach several thousands in an area of 10 cm². Close to sewage outfalls, they are typically very abundant but low in species diversity. The spatial distribution of all benthic species is very patchy. This may be related to asexual reproduction (known only for benthic species) and the consequential limited range of migration of offspring from the parent. Benthic foraminiferans become relatively more important with increasing water depth, possibly due to a competitive advantage they have over metazoans in their ability to rapidly exploit seasonally deposited phytodetritus. In oxygen minimum zones along the continental margins of tropical oceans, they can, because of their relatively small size, tolerate low oxygen conditions better than can metazoans. Also, certain taxa (e.g., *Bolivina* and *Uvigerina*) seem to be adapted for life in oxygen-depleted waters.

Foraminiferans in the deep-sea benthos are often abundant (typically hundreds per 10 cm²) and diverse (species richness may exceed that of nematodes), and they are now regarded as major components of the fauna in this zone (Gooday *et al.*, 1998). Because they consume bacteria and detritus, they probably act as a link in the food chain to higher trophic levels in the benthos. Very small species (30–63 µm) are common, but the dominant fauna > 500 µm in central oceanic regions (and particularly at depths greater than the carbonate dissolution depth of ~4000 m) are large agglutinated foraminiferans, especially the komokiaceans, which have complex anastomosing networks of tubules. In the benthos underlying the oligotrophic waters of the central North Pacific, the biovolume of komokiacean tests may greatly exceed the biovolume of metazoans. However, the amount of protozoan biomass in komokiacean tests is relatively small, and it may be even less than that of the metazoans that also occupy the test. *Edgertonella floccula* consists of a network of branching agglutinated chambers buried in a large (2–8 mm) inorganic mudball that it shares with cohabiting metazoans. This foraminiferan is one of the most abundant meiobenthic animals in some areas of the abyssal northeast Atlantic. Other deep-sea agglutinated foraminifera (e.g., *Bathysiphon* and *Hyperammina*) may even reach several centimeters in length, and some species stand vertically in the sediment and project into the overlying water, in which they presumably feed. Many of the common deep-sea foraminiferan species are probably cosmopolitan in their distribution.

The xenophyophoreans are another deep-sea group about which relatively little is known. They live in agglutinated, often fragile tests (typically 1–10 cm in length) and they too probably feed on sedimented detritus. Abundances of hundreds per square meter have been reported. The multinucleate protoplasm is enclosed within a labyrinthine organic tube encrusted with foreign particles. The organism also contains numerous crystals of barium sulfate, which have no obvious function. Growth is episodic, with intervening periods of

months of inactivity. They have no confirmed fossil record, although they often use the sedimented shells of the planktonic foraminiferan *Globigerina* to strengthen their tests (as in *Homogammina maculosa*).

Foraminiferan fossils are useful for biostratigraphy because (1) their sedimented remains are abundant (e.g., in the “*Globigerina* ooze” which covers much of the abyssal plain beyond the continental shelves), (2) individual shells are identifiable to species level, and (3) their remains allow determination of sea surface paleotemperature. Seawater and calcite differ in their ¹⁸O/¹⁶O ratio. This difference increases with temperature, so the ratio is used to estimate the water temperature at the time the calcite was deposited in the fossil foraminiferan shell. This estimate can then be compared with the established correlation between the temperature of water mass and the extant species it typically supports. Much of this work is supported financially by the oil exploration industry.

Actinopod amebae all have axopods, which are stiffened ray-like pseudopodia that radiate from the cell body (Figure 1). They also have a peripheral network of filopodia, which are long, thin, sticky pseudopodia used for trapping food organisms that make chance contact. There are three principal groups: (1) radiolarians, consisting of the polycystines with perforated spiny lattice skeletons of silica and the phaeodareans with skeletons of hollow tubes and spines; (2) acantharians with skeletal spines of strontium sulfate radiating from the center of the organism; and (3) heliozoans, which often lack an internal mineral skeleton (although some species produce skeletal spicules which are either organic or siliceous) and superficially resemble polycystine radiolarians. All actinopod protozoa, apart from a large number of heliozoans, are exclusively planktonic in deep oceanic water.

Radiolarians (Figure 1) and acantharians range in size from ~30 µm to several millimeters in diameter. Colonial radiolarians (e.g., *Collozoum longiforme*), which occur as gelatinous cylinders with diameters of several centimeters, can reach 3 m in length. Typical food items include diatoms, tintinnids and other ciliates, crustacean larvae, and other zooplankton, all of which are trapped in the peripheral network of axopods and filopodia. The smallest species may eat bacteria (Anderson, 1983).

Dinoflagellate (*Symbiodinium*), chrysomonad, and prasinomonad symbionts are associated with many polycystine radiolarians. They probably contribute to the host carbon metabolism because the consortium can last many weeks without exogenous food. The symbionts are carried about in the host's cytoplasmic streaming, gathering in the peripheral filopodia at dawn and withdrawing inside the host shell at sunset. The phaeodareans that live near the ocean floor do not have algal symbionts. Radiolarians are found at all water depths down to ~8000 m, although they are most abundant and diverse between 200 and 2000 m (Anderson, 1983). No benthic species are known. Like planktonic foraminiferans, each radiolarian species inhabits an oceanic water mass that lies within a particular temperature range. Moreover, because of the immense depths to which living radiolarians sink, those species living in surface waters at high latitudes are also found in the tropics but in very deep and cool waters. As a consequence, the species assemblages found in surface waters give a misleading impression of radiolarian biogeography. It is believed that

radiolarians may be transported in very deep oceanic waters between high northern and high southern latitudes.

Radiolarian abundance and productivity increase in warmer waters. Abundance may be almost nil in the surface waters of the Antarctic, up to 50 m^{-3} in the Caribbean and Gulf Stream, and up to several thousand per m^3 in the Gulf of Mexico. Colonial radiolarians are much less abundant. In the Sargasso they are considered abundant if represented by more than one colony per 100 m^3 . Acantharians can reach relatively high abundances (up to $25\text{--}35 \text{ l}^{-1}$) and they are often the most abundant of the planktonic shelled amebae, but relatively little is known about living organisms because as soon as they are collected the fragile cell membrane breaks and the strontium sulfate skeleton dissolves. Radiolarians are important stratigraphic tools, and skeletal morphology is the main characteristic used to identify species; hence, much information is available on the diversity of radiolarian skeletons.

The heliozoans are predominantly a freshwater group. They resemble functionally the radiolarians, especially with respect to their diffusion feeding. They span a wide size range. Some (e.g., *Actinosphaerium*) can be $> 1 \text{ mm}$, but most species are $\sim 40 \mu\text{m}$ (*Actinophrys*). Depending on their size, different species feed with little apparent selectivity on algae, flagellates, ciliates, and rotifers. Small heliozoan species account for most of the biomass of ameboid protozoa in the freshwater plankton. Most, however, are attached to or loosely associated with sediment and other submerged surfaces (Page and Siemensma, 1991).

Flagellated Protozoa

There is a little consensus on how to classify the flagellates, and they are here divided into broad functional groups (Figure 2). Heterotrophic flagellates are fundamentally important because they are abundant (there are seldom less than 1000 ml^{-1} , even in the plankton) and because their grazing activities are largely responsible for controlling the abundance of bacteria in aquatic environments. In some taxonomic groups, all species are exclusively heterotrophic (e.g., choanoflagellates and bodonids); others contain many mixotrophs (e.g., the euglenids and chrysomonads), whereas the haptomonads and cryptomonads are dominated by phototrophs and only a minority are capable of phagotrophy. In the past 25 years, a large diversity of heterotrophic flagellates has been discovered. Most of these are choanoflagellates, chrysomonads, euglenids, or bodonids. Some of the more easily recognized species (e.g., *R. nasuta*) have been recorded from a wide range of habitat types in marine, freshwater, and terrestrial environments (Patterson and Larsen, 1991; Lee and Patterson, 1998).

Many heterotrophic flagellates are anaerobes, including intestinal parasites of man (e.g., *Giardia intestinalis*), but free-living diplomonads (*Hexamita* and *Trepomonas*) and *Retortamonas* are relatively common bacteria feeders in organically enriched anoxic waters and sediments. Some anaerobic flagellates have hydrogenosomes, the anaerobic derivatives of mitochondria. Almost all of these are endosymbionts or internal parasites of animals. They are also known as parabasalians and include many of medical or economic

importance, e.g., the human parasite *Trichomonas vaginalis* and *Trichomitopsis*, which degrades cellulose in the hindgut of termites and other wood-eating insects and also supports endosymbiotic methane-producing bacteria (termites may be responsible for a globally significant flux of methane to the atmosphere) (Fenchel and Finlay, 1995).

Most choanoflagellates are small ($< 10 \mu\text{m}$), with a feeding filter that forms a collar around the single anterior flagellum. The flagellum creates the water current that flows through the filter. Choanoflagellates are exclusively phagotrophic and either solitary (e.g., *Monosiga*) or colonial (e.g., *Sphaeroeca*). They are important grazers of the smallest suspended bacteria, especially in the marine plankton (e.g., *Salpingoeca*, *Stephanoecca*, and *Parvicorbicula*).

Euglenids usually have two flagella which emerge from a small anterior pocket. This is a large group of planktonic and benthic protozoa, common in both fresh and marine waters. Species associated with surfaces typically keep one trailing flagellum in contact with the substrate, whereas the other pulls the cell forward. Many species are green and phototrophic (e.g., *Euglena*), but there is a great diversity of phagotrophs (e.g., *Astasia*, *Petalomonas*, *Entosiphon*, and *Notosolenus*). These are especially common in marine shallow-water sediments, in which they graze on bacteria. All bodonids are small flagellates with characteristic heterodynamic flagella (e.g., *Bodo* and *Rhynchomonas*). They are almost always found in organically polluted (even anoxic) waters or soils that are rich in bacteria, on which they feed. Many closely related ("kinetoplastid") flagellates are parasites: *Ichthyobodo* causes costiasis in freshwater fish and the "trypanosomatids" are important parasites of man (*Trypanosoma brucei* causes sleeping sickness). In heterokont flagellates, each organism has two flagella – one hairy and one smooth, with the former creating the water current that brings mainly bacterial food to the (filter-feeding) flagellate. They include the bicosoecids that live in a lorica (*Bicosoeca*) or are naked (*Cafeteria* and *Pseudobodo*), that may be stalked or colonial, and which resemble the mixotrophic loricate chrysomonads (e.g., *Dinobryon*).

In the phagotrophic chrysomonads (e.g., *Paraphysomonas* and *Spumella*), the chloroplast is essentially vestigial (and the cell is colorless). Functional types range from heterotrophs (e.g., *Paraphysomonas*) to mixotrophs (e.g., *Dinobryon* and *Uroglena*) and those that are predominantly phototrophs (e.g., *Synura* and *Mallomonas*). Chrysomonads are the most abundant heterotrophic flagellates in the freshwater plankton. The helioflagellates (also referred to as "pedinellid stramenopiles," e.g., *Actinomonas*, *Pteridomonas*, and *Ciliophrys*) are filter or diffusion feeders that superficially resemble heliozoa or choanoflagellates.

The haptomonads are typically photosynthetic, biflagellated organisms. They include the coccolithophorids and the prymnesiophytes, and some (e.g., *Emiliania*) are often abundant in the marine euphotic zone. They have an additional flagellar appendage known as the haptonema. In the marine *Chrysochromulina*, this is used in food uptake, but in *Prymnesium*, which has a very short haptonema, ingestion of food (dinoflagellates, chrysomonads, and green algae) is by means of a posterior pseudopodium. Prey organisms may be immobilized by toxins prior to ingestion (toxic bloom-forming species of *Prymnesium* are responsible for fish kills). The scale

Figure 2 A selection from the variety of form and function in flagellated protozoa. (1) a choanoflagellate with bacterial food trapped on the external surface of the collar filter (*Monosiga*; body + collar ~0.015 mm); (2) a bacteria-feeding helioflagellate (*Pteridomonas*; body 0.007 mm); (3) a phagotrophic euglenid (*Dinema*; ~0.03 mm) with an ingested diatom; (4) a marine heterotrophic dinoflagellate (*Protoperidinium*; ~0.06 mm) with a diatom trapped in its feeding veil; (5) a free-living, bacteria-feeding, anaerobic diplomonad (*Hexamita*; body ~0.008 mm); (6) a small heterotrophic (bacteria-feeding) cryptomonad flagellate (*Goniomonas*; ~0.008 mm); (7) a heterotrophic, typically bacteria-feeding, chrysomonad flagellate (*Spumella*; body ~0.008 mm); (8) a bacteria-feeding bodonid (*Rhynchomonas*; body ~0.005 mm).

and importance of phagotrophy in freshwater haptomonads is unclear.

Most cryptomonads are yellow-brown and phototrophic, with two flagella of similar length (e.g., *Cryptomonas*). They are especially common in fresh waters. Heterotrophic species either lack plastids (*Goniomonas*) or have a plastid that is devoid of photosynthetic pigments (*Chilomonas*). Colorless species can be relatively abundant, especially when associated with benthic detritus.

The heteromitids and cyathobodonids represent a varied assemblage of small, poorly studied flagellates (e.g., *Apusomonas*, *Heteromita*, *Cercomonas*, *Cyathobodo*, and *Kathablepharis*), some of which (e.g., *Cercomonas*) produce pseudopodia to ingest bacteria. Others secrete a stalk (*Cyathobodo*) to attach the cell to the substrate. Many are common in soil. Others feed mainly on bacteria in the freshwater plankton (e.g., *Kathablepharis*, which also feeds on small algae) and on sediment surfaces. The percolozoans are a diverse collection of bacteria-feeding organisms, including ameboflagellates (e.g., *Naegleria*), the filter-feeding flagellate *Percolomonas*, and anaerobic flagellates with hydrogenosomes and endosymbiotic methanogens (*Psalteriomonas*).

Dinoflagellates are best known as a large group of photosynthetic flagellates and for the ability of some species to cause "toxic blooms" and "red tides" (*Protogonyaulax* causes paralytic shellfish poisoning). However, about half of all known marine species lack chloroplasts. Some of these (in the genera

Gymnodinium and *Amphidinium*) feed on cryptomonads and sequester their chloroplasts, thus transforming themselves into mixotrophs. Moreover, many typically photosynthetic species can become mixotrophs through their ability to ingest particulate food. The nonphotosynthetic and mixotrophic species are referred to collectively as heterotrophic dinoflagellates. These can be quantitatively important in marine food webs, especially as consumers of diatoms. Some species are benthic, but little is known about these. The diversity of heterotrophic species in fresh waters is much less, and it is known mainly from the genera *Katodinium*, *Peridinium*, *Gymnodinium*, and *Ceratium*. This may be due in part to the relative rarity in fresh waters of large, chain-forming diatoms – a typical food item of many marine dinoflagellates. These large food items are trapped and digested externally in a pseudopodial feeding veil or pallium. This explains why it has often been difficult to recognize ingested organisms within dinoflagellates. Other heterotrophic dinoflagellates use a feeding tube known as a peduncle. The common freshwater dinoflagellate *Peridiniopsis berolinensis* uses such a tube to ingest the fluid contents from injured and dying protists and small metazoans.

The number of marine dinoflagellate species with a recorded capacity for phagotrophy is increasing rapidly. These include thecate species (e.g., the peridinioids) previously considered to be incapable of phagotrophy. It is widely believed that most dinoflagellates – at least in marine environments – may be capable of phagotrophy. Heterotrophic

dinoflagellates (e.g., *Oblea*, *Polykrikos*, *Heterocapsa*, and *Protoperidinium*) can dominate the protozoan biomass in coastal and oceanic waters, in which they feed on bacteria, flagellates, diatoms, other dinoflagellates, and ciliates. Their biomass can be approximately the same as that of ciliates, and the two groups may compete with each other for food (although the size range of dinoflagellates is slightly greater – from 3 or 4 μm in *Gymnodinium simplex* to 2 mm in *Noctiluca*, with the majority in the size range 20–200 μm). Also, most planktonic ciliates are incapable of ingesting the large diatoms that are consumed by dinoflagellates.

Almost all stony and stinging corals (Cnidaria) in shallow tropical waters harbor photosynthetic dinoflagellates (especially *Symbiodinium*) as symbionts. These consume carbon dioxide and bicarbonate. This promotes calcium deposition in the external skeletons of their hosts and may enhance the rate with which coral reefs are built. In the marine plankton, outbursts of parasitic dinoflagellates are sometimes associated with the collapse of zooplankton populations. The parasite *Ichthyodinium chabellardi* destroys the eggs of sardines, *Blastodinium* sp. in the copepod gut castrates its host, and *Gonyaulax catenella* (a dinoflagellate that can cause red tides) is parasitized by another dinoflagellate (*Amoebophrya ceratii*). The fossil record of dinoflagellate cysts extends over the past 220 million years, and they have a role as biostratigraphic tools.

Dinoflagellates in the marine plankton exhibit latitudinal cosmopolitanism, such that a morphospecies occurs in a circumglobal belt within fairly broad latitudinal limits which correspond to a specific temperature range in the surface waters. The recorded species richness is greatest in tropical marine waters.

Ciliated Protozoa

This diverse and distinctive group uses cilia for locomotion and feeding (Figure 3). They demonstrate a considerable adaptive radiation of feeding mechanisms and cell morphologies (e.g., the ribbon-shaped forms *Tracheloraphis* and *Geleia* adapted for life in the marine interstitial) (Fenchel, 1987). The smallest species tend to feed on bacteria-sized particles and the larger species on unicellular algae, filamentous cyanobacteria, other protozoa, and even rotifers and other microzooplankton. The raptorial feeders (e.g., *Prorodon*) use a simple mouth to catch diatoms, dinoflagellates, and other large food items individually; some (e.g., *Lacrymaria*) kill motile prey, whereas others (e.g., *Chilodonella*) “hoover” diatoms and other elongate food particles from surfaces. The filter feeders (e.g., *Cyclidium*) use fine-mesh filters to sieve suspended bacteria, and some of these ciliates (e.g., *Paramecium* and *Tetrahymena*) thrive in habitats with very high bacterial concentrations. Other ciliates (e.g., *Pleuronema* and *Tintinnopsis*) use coarser filters to collect small algae. In many ciliates (e.g., *Oxytricha*, *Aspidisca*, and *Strombidium*), a row of membranelles generates a water current and acts as a relatively coarse feeding filter, and some of these ciliates (e.g., *Euplotes*) feed most efficiently if they are raised on cirri (fused cilia). Many ciliates are typically sessile and aligned perpendicular to the substrate (e.g., *Stentor* and *Vorticella*). Diffusion feeders (e.g., *Podophrya* and other Suctorina) catch

swimming prey (usually other protozoa) that collide with their sticky tentacles.

More is probably known about the biodiversity and ecology of free-living ciliates than any other protozoan group. There are several reasons for this, including the distinctive and immediately recognizable ciliate morphology and swimming behavior and the relative ease with which many species can be cultured. They are a group of predominantly free-living protozoa. A few are parasites (e.g., *Ichthyophthirius* infects fish and there is one human endoparasite of minor importance – *Balantidium coli*), but most species are either free-living or harmless commensals of aquatic invertebrates (the ciliate epifauna of marine crustaceans is particularly diverse). Free-living species are known from all natural aquatic habitats in which temperatures are $<45^\circ\text{C}$, including oceanic sinking detritus, freshwater and marine sediments, anaerobic municipal landfill sites, and sewage treatment plants. They are abundant (up to $\sim 106\text{ ml}^{-1}$) in activated sludge plants, in which they consume bacteria and also flocculate bacteria and other suspended particulate matter. These activities aid the clarification of the effluent and the formation of sludge. About a dozen ciliate species are frequently recorded in used-water treatment plants, although more than 200 ciliate species have been recorded. Ciliates also have a role as indicators of the level of organic pollution in river water (Corliss, 1979, 2000; Lynn, 2008).

Most ciliates are in the size range 0.02–2 mm, so they are generally larger than the heterotrophic flagellates and other nanoplankton (0.002–0.02 mm) on which many of them feed. Planktonic ciliates are relatively abundant ($1\text{--}100\text{ ml}^{-1}$) and important grazers of nanoplankton in marine and fresh waters. They are probably key grazers within the microbial loop which is responsible for the rapid remineralization of organic matter in the water column. The diet of planktonic metazoans includes ciliates, although the quantitative significance of this link is unclear. Benthic ciliates are often abundant ($>1000\text{ ml}^{-1}$) and usually the most important grazers in freshwater sediments (especially in lakes) and marine sandy sediments of inshore waters.

Many ciliate species harbor prokaryotic or eukaryotic symbionts. At the oxic–anoxic boundary in the water column of lakes, most ciliates may harbor sufficient endosymbiotic algae (*Chlorella*) to render the consortia capable of net photosynthesis in dim light. The marine interstitial ciliate *Kentrophoros* carries ectosymbiotic chemolithotrophic sulfide-oxidizing bacteria, and most anaerobic ciliate species harbor methanogenic bacteria that act as a sink for (potentially inhibitory) H_2 produced by the ciliate. The endosymbiotic nonsulfur purple bacteria in the anaerobic ciliate *Strombidium purpureum* use waste H_2 from the ciliate as a reductant for photosynthesis. Most marine anaerobic ciliates carry ectosymbiotic sulfate-reducing bacteria. (Fenchel and Finlay, 1995)

Many ciliate species are microaerobic, and they seek out the (microbe-rich) oxic–anoxic boundary in sediment or the water column. Some of these species are facultative anaerobes (in the genera *Cyclidium*, *Euplotes*, *Strombidium*, and *Paranophrys*). There are approximately 70 known species of anaerobic free-living ciliate species, mainly in the genera *Metopus*, *Caenomorpha*, *Saprodinium*, *Epilxella*, *Trimyema*, and *Plagiopyla*. It is likely that all these contain hydrogenosomes (Fenchel and Finlay, 1995).

Figure 3 A selection from the variety of form and function in ciliated protozoa. (1) a bacteria-feeding tetrahymenid (*Tetrahymena*; length ~ 0.05 mm); (2) a small scuticociliate (*Cyclidium*; length ~ 0.02 mm) filter feeding on bacteria; (3) a bacteria-feeding colpodid ciliate (*Colpoda*; length ~ 0.02 mm) from soil; (4) an anaerobic, typically benthic plagiopylid feeding on bacteria (*Plagiopyla*; length ~ 0.1 mm); (5) a large haptorid (*Dileptus*; length ~ 0.4 mm) with toxicysts used to kill motile prey (flagellates and other ciliates) prior to ingestion; (6) a planktonic, loricate, diatom-feeding tintinnid (*Tintinnopsis*; length ~ 0.1 mm); (7) a gymnostome ciliate (*Coleps*; length ~ 0.07 mm) about to ingest a dinoflagellate; (8) a diatom-feeding karyorelictid (*Remanella*; length ~ 0.12 mm) typical of the marine interstitial; (9) a “hoover-feeding” cyrtophorid (*Chilodonella*; length ~ 0.04 mm) ingesting a diatom; (10) a planktonic oligotrich (*Halteria*; diameter ~ 0.04 mm) filter feeding on small algae; (11) a “diffusion-feeding” suctorian (*Podophrya*; diameter ~ 0.04 mm) with a flagellate trapped on a feeding tentacle.

Anaerobic ciliates also live as endocommensals in the enlarged forestomach (rumen) of ruminants and in the cecum of other mammals with postgastric fermentation. It is unlikely that any of these ciliates (e.g., in the genera *Dasytricha*, *Entodinium*, and *Polyplaxton*) are capable of a free-living existence. Rumen ciliates are typically extremely abundant (10^5 – 10^6 ml $^{-1}$ of rumen liquor). They consume bacteria and microscopic fragments of grass and other plant material. Some species are capable of degrading cellulose and other structural carbohydrates, and the endosymbiotic methanogenic bacteria in some species contribute to the methane emitted from the ruminants. The economic significance of such large numbers of ciliates living in the rumen is unclear.

Ciliates also live in soil, in which all species are probably capable of producing desiccation-resistant cysts (e.g., *Colpoda*). The abundance of active ciliates in soil is extremely variable and reflects repeated cycles of cyst formation and excystment in response to fluctuating physical factors such as the level of soil moisture. Many species found in soil are frequently found in other (predominantly freshwater) habitats, although only about 200 ciliate species have been described from soil.

Others

The following are often referred to as protozoa. Because they are endocommensals or parasites, or incapable of phagotrophy,

they do not fall within the definition of protozoa used here (i.e., free-living unicellular phagotrophs). They are mentioned briefly for the sake of completeness but are excluded from Table 1.

Chytridiomycetes, oomycetes, and hyphochytriomycetes have the typical fungal characteristics of saprotrophic (absorptive) nutrition and cell walls in the vegetative state. Some are economically important (the oomycete *Phytophthora infestans* causes potato blight). The plasmodiophorids are cell wall-free endoparasitic slime molds (*Plasmodiophora brassicae* causes club root disease in cabbages). The labyrinthulids (e.g., the “slime net” *Labyrinthula*) feed saprotrophically, especially on marine algae, and form complex branching colonies of spindle-shape cells that move through slime channels. All five groups reproduce by means of unicellular flagellated zoospores (hence, they are also known as “zoosporic fungi”).

The opalinids superficially resemble ciliates, but all are mouthless endocommensals living in the hindgut of amphibians and some fish (Lee et al., 2000). The microsporidians are a large group (~800 species) of intracellular parasites of animals and other protozoa. They extrude a tubular filament through which the spore is injected into the host cytoplasm. They are believed to be highly derived fungi rather than early diverging eukaryotes. The haplosporidians are a small group of parasites of aquatic invertebrates, notably marine mollusks, and the parabasalans (anaerobic flagellates with hydrogenosomes, e.g., *Trichomonas*) are all parasites, with one or two possible exceptions (*Pseudotrichomonas*).

The organisms now referred to as apicomplexans used to be an important component of the sporozoans. All are intracellular parasites of animals, and many cause life-threatening diseases of man. They share the distinctive morphological feature of an apical complex at certain stages in the polymorphic life cycle. The degree of host specificity of many apicomplexans is not known. They include the gregarines that infect insects, marine polychaetes, and other invertebrates (e.g., *Monocystis* in earthworms), and also the “coccidian” parasites including *Toxoplasma gondii* (the domestic cat is the final host, but intermediate infection in the human can cross the placenta) and about 1050 species of *Eimeria* infecting mammals, chickens, and other farmed birds. *Cryptosporidium* is an apicomplexan, and eight species are known that infect the digestive and respiratory systems of vertebrates. *Cryptosporidium parvum* infects humans and cattle, and waterborne transmission of oocysts is thought to complete the fecal–oral cycle. Infection can cause life-threatening diarrhea in immunocompromised humans. *Cryptosporidium* may be sufficiently different from other coccidians to warrant creation of the new higher taxon “cryptosporidia.” *Plasmodium*, the causative agent of malaria, is an apicomplexan, as is *Pneumocystis*, which is an enigmatic parasite that can persist in the human lung for long periods. *Pneumocystis carinii* (currently renamed as *Pneumocystis jirovecii*) causes *Pneumocystis* pneumonia in HIV patients. In the early 1970s, the organism was considered to be a fungus; in the early 1980s it was considered to be an apicomplexan, and by the late 1980s it was again

considered to be a fungus, possibly an ascomycete. Confusingly, it can resemble *Cryptosporidium* when viewed with the light microscope. There are approximately 4000 nominal species of apicomplexans.

The Myxozoans are a large group (~1200 species) of parasites, of which the myxosporidians are important parasites of farmed fish (*Myxobolus cerebralis* causes “torsion disease” in trout). During their life cycle they show both protozoan and metazoan characters. Recent gene sequence data (18S rDNA) indicate that myxozoans are grossly modified and simplified metazoans of the phylum Cnidaria (Siddall et al., 1995).

Glossary

Barophile Pressure-loving bacteria.

Cryobiosis Anabiosis (latent life) due to freezing.

Endolithotrophic Living inside rocks, usually sandstone.

Homeophasic adaptation The adaptation of the membrane to maintain the bilayer phase.

Meltwater Ice or snow melted by radiant energy in the polar regions.

Permafrost Ground (ice, bedrock, and soil) that remains frozen below 0 °C for more than 2 years.

Thermocline In the stratification of warm surface water over cold, deeper water, the transition zone of rapid temperature decline between the two layers.

Upwelling Transport of water from the deep ocean to the surface, replacing the surface water that has moved offshore.

Definitions and Historical Background

Psychrophilic bacteria are defined as cold-loving bacteria. Specifically, their cardinal temperatures are 20 °C for maximal growth, 15 °C or lower for optimal growth, and 0 °C or lower for minimum growth (Morita, 1975), and this definition is accepted by most microbiologists. The old definition of psychrophiles applied to those organisms that produced a visible colony in 1 week at 0 °C. However, it is important to recognize that there is a continuum of cardinal temperatures for the diverse microbes in nature. From an ecological standpoint, psychrotrophs and psychrophiles are both found in cold environments, but psychrophiles are not found at temperatures higher than 20 °C. This temperature was selected as the maximum temperature for growth based on the fact that laboratory temperatures in the United States are approximately 21 or 22 °C. In higher organisms, the cold-loving organisms are known as cryophiles.

Microorganisms capable of growing at 5 °C or lower are psychrotrophs, regardless of the optimum temperature for growth. The psychrotrophs are cold-tolerant bacteria, but their maximal growth temperature ranges above 20 °C and in many cases their optimal growth temperature is also above 20 °C. A better term for these organisms that withstand cold temperatures is psychrotolerant. However, because of common usage this term should be retained. For example, there are a few texts employing the term “psychrotrophs” in their title and this term is widely used by industry (mainly dairy and food), e.g., the normal souring of milk is due to psychrotrophs. Furthermore, precedence should be adhered to in keeping the name.

Bacteria capable of growing at 0 °C were first reported by Foster in 1887 and 1892. The source material for these bacteria were from fish, natural waters, foods, wastes, rubbish, soil surface, and intestines of fish. The lowest temperature at which bacteria can grow remains to be determined definitely and –12 °C is the lowest temperature reported. The term “psychrophile” was first used in 1902 by Schmidt-Nielsen. In 1903, Müller objected to this term because the organisms described actually grow well at higher temperatures. As a

result, cold-tolerant bacteria were called cryophile, Glaciale Bakterien, rhigophile, psychrotolerant, psychrocarcticus, psychrobe, thermophobic bacteria, facultative psychrophile, obligate psychrophile, and psychrotrophic. A review of the literature indicates that the organisms described were actually psychrotrophs (as defined previously) with the possibility of one psychrophilic exception. For many years, it was thought that there were no bacteria that could be termed psychrophiles, only yeasts and certain algae. The lack of refrigeration equipment in the early days added much to this confusion. Thus, the term psychrophile was considered a misnomer until true psychrophiles were isolated by three different laboratories in 1964. The confusion was ended when Morita (1975) defined the term psychrophile (as noted previously). For further details, Morita (1975) should be consulted.

The Environment and its Microflora

Eighty percent of the earth's biosphere is permanently cold and the average temperature of the earth is 15 °C. Permafrost occupies 20% of the earth's surface: 80% of Alaska, 50% of Canada, 20% of China, and 50% of Russia are covered by permafrost. However, the amount of microbiological research done on psychrophiles is extremely low compared to that done on thermophilic bacteria.

The polar regions comprise about 14% of the earth's surface. Approximately 71% of the earth's surface is ocean, and more than 90% (by volume) of the oceans are 5 °C or colder. Other cold environments include caves, the tops of mountains, certain rivers and streams, the upper atmosphere (10 °C or less at 1000 m, decreasing as the altitude increases), snow and ice, and the water below the thermocline of freshwater lakes; each has its own microbial flora (Baross and Morita, 1978).

Upper Atmosphere

Air samples collected near the earth's surface up into the stratosphere exceeding 27,000 m have shown the presence of viable bacteria, viable fungi, pollen, and other microscopic

particles. A high incidence of viable bacteria has been reported within the troposphere at approximately 10,000 m, where the temperature may be lower than -40°C . The highest incidence of bacteria appears to be at altitudes slightly higher than 10,000 m, where the temperature is lower than 10°C . Although this temperature is well within the cardinal temperature range of psychrophile and psychrotrophs, there are no reports of psychrophiles in the upper atmosphere. Furthermore, there is organic matter (cobalamin, biotin, and niacin) in the air but the concentration is very low. Thus, these organisms have the ability to resist starvation, drying, freezing, and radiation. These microbes can be the nucleation site for the formation of ice and snow.

However, in the lower atmosphere of the polar regions, nutrient agar plates were media exposed to the air and showed the presence of viable bacteria. Unfortunately, there are no reports of seawater-requiring psychrophilic bacteria from air samples. In all probability, the atmosphere, especially above the polar regions, does contain psychrophiles and psychrotrophs.

Caves

There are many glaciated and subterranean caves in which the permanent temperature is about 10°C to below freezing. In addition to the low temperature, there is an absence of light, low levels of organic material, and relatively high moisture. Generally, there is an absence of psychrophiles in these caves, but psychrotrophs are found.

Arctic

The similarities of the Arctic and Antarctic polar regions are the continuous sunlight during the summer and the total lack of it during the winter, the presence of sea ice during much or all of the year, and the cold temperature. On the other hand, they differ in that the Arctic has major riverine inputs, but the Antarctic does not. They also differ in their landmasses, topographical features, large-scale water transport features, and the magnitude of nutrient supply. Relative microbial activities, as measured by the incorporation and respiration of ^{14}C -labeled glucose and glutamic acid (called the heterotrophic potential method by marine microbiologists and substrate-induced respiration by soil microbiologists), are comparable in both the Arctic and Antarctic near-shore water. These measurements were made by the same laboratory working at different times in both regions.

Antarctic

About 98% of the surface of Antarctica is ice, leaving 2% of the continent ice free. The lowest temperatures on Earth occur on this continent and it has the lowest precipitation and relative humidity levels, making it the driest area on Earth. As a result, dry valleys and ice-free areas occur in addition to many other types of environments (e.g., temporarily and permanently ice-covered lakes, transient rivers and streams, oligotrophic lakes, and moss and peat bogs), with all sharing low temperatures. Freezing, like drying, will produce hypersaline lakes, both thallosaline (seawater derived) and athallosaline (brine derived

from geological and geochemical sources). For a few weeks of the austral summer flowing liquid water can occur, producing ice melts around the margins of frozen lakes. Study of the microbiology of these meltwaters has just begun. In all probability, psychrophilic bacteria, which are also alkalophilic and/or halophilic, will be found. Even in the dry valleys of Antarctica, numerous psychrotrophs and mesophiles have been isolated. Because freezing is equivalent to drying, the indigenous microflora have the ability to tolerate low temperatures in addition to being xerotolerant (i.e., able to live in very dry environments). Within sandstones of the dry valleys, the presence of cryptoendolithotrophic bacteria has been shown along with that of algae (Friedmann, 1993). These bacteria, mainly cyanobacteria, only grow during the austral summer of the Antarctic when the temperature, due to solar radiation, rises sufficiently high to produce liquid water. It should also be mentioned that there is a greater predominance of cyanobacteria and psychrophiles in the Antarctic than in the Arctic.

Permafrost

The discovery of microorganisms in permafrost was initiated in the 1930s in the Trans-Baikal and North Ural regions, Central Yakutia, and Arctic islands (Gilichinsky, 1995). Permafrost cores yielded numerous microbes. Microbes have been reported in all the Arctic and Antarctic permafrost environments except in the lower strata of permafrost ice of Lake Vostok in Antarctica. This exception may be due to the techniques employed. Unfortunately, the early microbiologists did not recognize the abnormal thermolability of psychrophiles, and as a result psychrotrophs and mesophiles were mainly demonstrated. In the early literature, thermophiles (as high as 100 cells/g) were reported in Arctic permafrost (peat cores 10,525 years old). Viable microorganisms were reported from Holocene sedimentary deposits and Pliocene deposits (3–5 million years old). Viable fungi, spore-forming bacteria, and non-spore-forming bacteria were in the Antarctic ice sheet up to a depth of 300 m (11,600 years old) but not at 320 m (13,000 years old), whereas in a 107,000- to 200,000-year-old layer of glacier ice, viable organisms were found (Friedmann, 1993). In permafrost material millions of years old, thermophiles, mesophiles, and psychrophiles have been found (Vorobyova *et al.*, 1997). This ancient material does not have sufficient energy in it to keep the organism metabolizing for long periods of time; hence, one has to ask where the energy is coming from. In most cases, the energy supplied has been utilized since any ecological niche has a large number and consortium of microbes that utilize the energy source leaving the more recalcitrant material. This recalcitrant material, if used metabolically, will require exoenzymes to degrade it to its monomers so that it can be transported into the cell. In addition, many substrates that the cell utilizes require an active transport mechanism which also consumes energy. Because of this situation, microbes in ancient material, such as the deeper strata of permafrost, are in an anabiotic stage. Specially, the anabiotic stage is cryobiosis, brought about by the low temperature. However, the cells are also in a starvation-survival mode. Both processes generate stress proteins, some of which are shared. The Russian microbiologist

Omelyanski (1911) attributed the existence of microbes in ancient cold environments to anabiosis, a term not employed by most microbiologists. Nevertheless, one always must ask "where is the energy?"

For further information concerning viable microorganisms in permafrost, Gilichinsky (1994) should be consulted.

Oceans

The area below the thermocline is approximately 5 °C or colder. Thus, the deep sea is permanently cold. Gradually, as the higher latitudes are approached, the depth of the thermocline decreases until it is at the surface of the ocean. In the deepest portions of the oceans (trenches and deeps), barophiles can be isolated that are also psychrotrophic or psychrophilic. At the edge of the ice where ice is melting or being formed, there is a sea ice environment with an associated microbial community. All types of microorganisms can be demonstrated in waters below the thermocline, mainly because there are many different types of habitats available.

Sea Ice

Where the seawater is being frozen, a sea ice microbial community resides. The freezing process helps concentrate the dissolved nutrients, and when the ice melts the concentrated nutrients in the ice are released so that sufficient energy is present to permit the growth of this microbial community. Thus, this community is influenced mainly by the onset of spring and winter. Within this sea ice community a variety of bacteria are found displaying numerous morphological types. Seventy percent of the bacteria in the sea ice community are free living, and ice nucleation bacteria can also be found. Various pigmented and gas vacuolate bacteria are also present and 65% of the epiphytic bacteria are found associated with the diatom *Amphiprora*. The best growth response of the sea ice microbial community occurs between 5 and 10 °C.

Biodiversity of Psychrophiles

The first known species of psychrophiles described taxonomically are *Vibrio* (*Moritella* gen. nov.) *marinus* MP-1 and *Vibrio* (*Colwellia* gen. nov.) *psychroerythrus*, both isolated in 1964. The biodiversity among psychrophiles in the various cold environments has yet to be studied extensively. Nevertheless, the various species within the genera *Achromobacteria*, *Alcaligenes*, *Altermonas*, *Aquaspirillum*, *Arthrobacter*, *Bacillus*, *Bacteroides*, *Brevibacterium*, *Clostridium*, *Colwellia*, *Cytophaga*, *Flavobacterium*, *Gelidibacter*, *Methanococcoides*, *Methanogenium*, *Methanosarcina*, *Microbacterium*, *Micrococcus*, *Moritella*, *Octadecabacter*, *Phormidium*, *Photobacterium*, *Polaribacter*, *Polaromonas*, *Pseudomonas*, *Psychroserpens*, *Shewanella*, and *Vibrio* have been found to be psychrophilic. Even a psychrophilic methanotroph (resembling *Methylococcus*) has been isolated from the tundra. Both the domains *Bacteria* and the *Archaea* are represented in the various genera listed. To date, only the genus *Moritella* appears to be composed of psychrophiles only. However, it should be noted that many species of reported

psychrophiles do not meet the definition given in this article. Because of this situation, the cardinal temperatures of many psychrophiles need to be determined.

All psychrophilic and barophilic bacteria that have been cultivated belong to the subdivision γ -Proteobacteria: *Shewanella*, *Photobacterium*, *Colwellia*, *Moritella*, and a new group designate containing strain CNPT3 and *Alteromonas haloplanktis*. The indication is that the combined barophilic and psychrophilic phenotype evolved independently in the different γ -Proteobacteria genera (DeLong *et al.*, 1997).

Several psychrophilic, gas vacuolate bacteria have been isolated from the sea ice and water from both the Antarctic and the Arctic. These include representatives belonging to the α -, β -, and γ -Proteobacteria subdivisions as well as the Cytophaga-Flavobacterium-Bacteroides phylogenetic group (Gosink *et al.*, 1998). These results demonstrate a wide range of phylogenetic diversity capable of psychrophily across the domain Bacteria.

Incredibly, as much as 30% of the marine picoplankton (planktonic organisms with an average diameter of 0.2–2.0 μ m) from both polar and temperate coastal waters are also Archaea (i.e., archaeoplankton) and the majority of these are associated with the Crenarchaeota. Despite this cosmopolitan distribution in the world's oceans, little is known about the physiological properties of these archaeoplankton, with the exception that they are hypothesized to potentially be psychrophilic based on the marine sponge symbiont *Cenarchaeum symbiosum* (Preston *et al.*, 1996). However, similar archaeal phylotypes have been located at a deep-sea hydrothermal vent system (Moyer *et al.*, 1998) in waters with an environmental temperature of 15–30 °C. Many hyperthermophiles are members of the Archaea that can utilize H₂ as an energy source, and recently *Methanogenium frigidum*, a psychrophilic, slightly halophilic, H₂-using methanogen, was isolated from the perennially cold, anoxic hypolimnion of Ace Lake, Antarctica (Franzmann *et al.*, 1997). Although it may be too early to state that this may be an indication of the evolutionary processes affecting both hyperthermophiles and psychrophiles, this does demonstrate that members of the domain Archaea are also capable of the psychrophilic lifestyle and that further research is needed. The main deterrent is the lack of isolation of psychrophiles, mainly because interest in this thermal group was lacking for many years. Yet to be isolated from the meltwater in the Antarctic are psychrophilic bacteria that are also alkaliphiles. Each body of water in the Antarctic has its own cations and anions and the salinity may be very high due to freezing of the water.

In any cold environment in which microbes have been isolated, many of the isolates are psychrotrophs. When all things are equal, the psychrophiles will outgrow the psychrotrophs at low temperature.

Evolution of Psychrophiles

The common approach used in microbiology is to apply phylogenetic analysis to establish evolutionary relationships among organisms and to use this as a framework for making inferences about community structure, making inferences about genetic and thereby inferred organismal diversity, and

(to a lesser degree) to infer physiological adaptation when applicable. This approach is possible due to the detailed theory of evolutionary relationships among the domains Bacteria, Archaea, and Eucarya that has emerged from comparisons of ribosomal RNA “signature” sequences. Most researchers currently infer that the earliest common ancestor to all three domains was a H_2 -metabolizing hyperthermophile based on the deepest branching lineages found in the domains Bacteria and Archaea (Pace, 1991). If we accept this premise, then the thermophiles must have evolved from the hyperthermophiles, followed by the mesophiles and finally the psychrophiles. This hypothesis has been challenged by criticism that the hot origin of life scenario is not compatible with the RNA world hypothesis (because of the instability of RNA at near water boiling temperatures) and/or by the argument that hyperthermophiles are not primitive but have instead successfully adapted to temperatures higher than the limits imposed on other life-forms (Forterre, 1996). In addition, dibiphytanyl ether lipids used in the formation of lipid “monolayer” cell membranes in hyperthermophilic Archaea were found in nonthermophilic members of the kingdom Crenarchaeota, which appear to be a major source of tetraether lipids in the marine planktonic environment (DeLong *et al.*, 1998). Recently, a nonhyperthermophilic earliest common ancestor was hypothesized based on the correlation between the G + C nucleotide content of ribosomal RNA sequences with the optimal growth rate temperature found in prokaryotes (Galtier *et al.*, 1999). If the nonhyperthermophilic hypothesis is presumed to be correct, it then implies that mesophiles were most likely the first to evolve with thermophily and psychrophily adaptations followed thereafter. Psychrophily undoubtedly has evolved multiple times, thereby giving rise to polyphyletic origins (i.e., psychrophilic members are contained within lineages spanning the divergence of divisions and domains).

A phylogenetic tree generated exclusively from SUU rRNA sequences of cultivated obligate psychrophiles demonstrates five major lineages spanning the prokaryotic domains of Bacteria and Archaea (Figure 1): the Crenarchaeota, the Euryarchaeota, the Flexibacter–Cytophaga–Bacterioides group, the gram-positive Bacteria group, and Proteobacteria. The majority of individual isolates are located in lineages contained either by the Flexibacter–Cytophaga–Bacterioides group or by the *Moritella*, *Colwellia*, and *Shewanella* subgroups of the γ -Proteobacteria.

Physiology of Psychrophiles (Metabolic Activities)

Psychrophiles were not isolated until 1964 mainly because of the fact that previous investigators did not recognize the abnormal sensitivity of this thermal class. Although it was known that most marine bacteria would not withstand the plating temperature of agar, microbiologists working in the Arctic and Antarctic did not take the precaution of keeping their sample material, media, pipettes, loops, and needles cold before use. Even for some psychrophiles, 10 °C is too warm and the organisms will expire.

Many assume that growth at low temperature is slow. This assumption was shown to be incorrect when *Moritella marinus* was reported to have a doubling times of 80.7 and 226 min at

15 and 3 °C, respectively. The lowest temperature recorded for growth of microorganisms is –12 °C, but there are unconfirmed reports of growth at –18, –20, and –34 °C for yeasts and fungi. Metabolic activity depends on the freezing properties of the cellular aqueous solutions and the liquid immediately adjacent to the cell. Aqueous solutions can be cooled to –10 to –20 °C before freezing occurs. Franzmann *et al.* (1987) recorded liquid water at –14.1 °C in Organic Lake, Antarctica. This liquid water naturally would be very saline since much of the water is freezing out. It is interesting to note that although *Halobacterium* and *Halomonas* are both halophilic as well as psychrophilic, no growth could be demonstrated in the liquid water from either Organic and Deep Lakes, Antarctica; hence, temperature was not the only limiting factor for growth. However, like most environments in the biosphere, the lack of other environmental or chemical conditions (mainly energy) usually prevents rapid growth of the microorganisms.

Enzymes

Unlike thermophiles, research on the physiology of psychrophiles has been neglected over the years. The few studies dealing with enzymes (and cytoplasmic proteins) from psychrophiles indicate that they are more thermolabile compared to their counterparts in mesophilic bacteria—their maximum, minimum, and optimum temperatures for activity are lower. However, most of these enzymes will operate several degrees above the maximum growth temperature of the psychrophiles. Malic dehydrogenase, the first enzyme from a psychrophile to be studied, obtained from cells of *M. marinus* was found to be stable between 0 and 15 °C and inactivation occurred between 15 and 20 °C. This organism’s optimum growth temperature is 15 °C and its maximum is 20 °C. If the enzyme is partially purified, inactivation at higher than 20 °C becomes very pronounced. Phosphofructokinase/glyceraldehyde-3-phosphate dehydrogenase complex, lactic dehydrogenase, hexokinase, and aldolase from this same organism lost activity when incubated for 1h to 35–40 °C. Surprisingly, glyceraldehyde-6-phosphate dehydrogenase was found to be stable at 26 °C; however, at 36 °C for 1h, it lost 90% of its activity. Triose-phosphate isomerase, a glycolytic enzyme, isolated from *Moritella* sp. strain ANT-300 (maximum growth temperature of 12 °C) is extremely heat sensitive and has a half-life of heat inactivation of 520s at 25 °C. Other enzymes that have been examined from psychrophiles include α -amylase, lipase, protease, alkaline phosphatase, and β -lactamase. As a general rule, the enzymes isolated from psychrophiles have not adapted entirely to correspond with the cardinal temperatures of the respective psychrophile cell. The abnormal thermoability of enzymes from psychrophiles is not the primary target of death from heat. Nevertheless, enzymes from psychrophiles are receiving more attention due to their possible industrial and biotechnological uses.

Membranes

In order for the cell to maintain its bilayer structure of membrane lipids, homeophasic adaptation has been proposed. This

Figure 1 Radial phylogenetic tree using the neighbor-joining distance method demonstrating the evolutionary relationships among cultivated psychrophiles. The tree was constructed using complete SSU rRNA sequences contained in the Ribosomal Database Project from the 99/99 release of Version 7.1 (<http://www.cme.msu.edu/RDP/html/index.html>), with the additions of *Cenarchaeum symbiosum* and *Moritella* sp. ANT-300. The scale bar represents 0.10 fixed mutations per nucleotide position.

adaptation permits the cell to function properly in terms of uptake, excretion, and regulation of intracellular ionic composition.

When psychrophiles are subject to temperatures above their maximum growth temperature, the cell leaks amino acids, DNA, and RNA, indicating that the membrane can no longer control its transport mechanisms. Furthermore, as the temperature reaches the maximum growth temperature or higher, the ability to respire is impaired. As a result, the cell expires.

Mesophiles and thermophiles cannot grow at low temperatures mainly due to the loss of membrane fluidity. This is why mesophiles (e.g., *Escherichia coli*) that have lost their membrane fluidity can no longer transport substrates into the cell. The fatty acid composition of the membrane changes in response to temperature. These homeophasic adaptations are often represented by changes in polyunsaturation, chain length, branching, cyclization, and often a combination thereof (Russell, 1992). Membranes of psychrophiles and psychrotrophs contain more polyunsaturated short chains and

branch and/or cyclic fatty acids than do mesophiles and thermophiles. In general, the membrane lipids are composed of an increasing amount of unsaturated fatty acids as the temperature decreases. Membrane fluidity can also be changed by *cis/trans* isomerization of the double bonds of fatty acids. Depending on the species in question, psychrophiles are generally endowed with a higher proportion of unsaturated fatty acids, especially hexadecenoic (16:1) and octadecenoic (18:1) acids, than mesophilic bacteria. The amounts of myristic acid (14:0) and palmitic acid (16:0) are higher in cells that are grown at higher temperatures. When grown at 0 °C, there is an increase in docosahexaenoic acid (22:6) and/or eicosapentaenoic acid (20:5) in some strains of psychrophiles and barophiles.

In order to make the membrane lipids more unsaturated when the temperature is lowered, a desaturase enzyme is used which acts on the acyl chain of the membrane lipids ((Russell, 1992). This desaturase activity is followed by temperature-dependent changes in fatty acid chain length

and branching mediated by additional synthesis. These metabolic activities all serve to maintain the fluidity of the cell membrane so that it can function properly. The foregoing data were obtained by using a psychrotroph; therefore, the ability to alter the fatty acid composition may be restricted to psychrotrophs and not psychrophiles.

It should be noted that when the psychrophile *Moritella* sp. strain ANT-300 was starved, there was induced qualitative and quantitative changes in fatty acids (e.g., fatty acid 16:1 increased from 42 to 62.5%). When starved, cells of *Moritella* sp. strain ANT-300 (as with many other bacteria) underwent fragmentation (i.e., reductive division), resulting in ultramicrocells. The starvation-survival state is the normal state of most microbes since most of the biosphere is oligotrophic. The oligotrophic nature of the psychrophile's environment is predominant since organic matter is lacking for the growth of heterotrophic psychrophilic bacteria. Thus, over most (~80%) of the earth's biosphere and in both polar environments, most of the microbes are in a starvation-survival mode most of the time.

Thus, it appears that various species of psychrophiles evolved from their mesophilic component and they inhabit permanently cold environments. Their upper and lower temperature limits are 20 and -12°C , respectively.

Glossary

Collectors curve Plot of the number of species found versus the number of individuals examined. The number of species generally rises very quickly at first and then levels off toward an asymptote as fewer new species are found per unit of individuals collected.

HTS High-throughput sequencing. A number of techniques that are able to automatically process many sequences in parallel, thus obtaining hundreds of thousands of sequences simultaneously.

LSU rDNA The gene in DNA that codes for the ribosomal RNA in the large subunit (LSU) of the ribosome. This is 23S rRNA in prokaryotes and 28S rRNA in eukaryotes.

Metagenomics An approach to collect and sequence all the genomes in a natural environment.

Morphospecies A species defined on the basis of morphology alone. This criterion has been traditionally used with many eukaryotic organisms, when information

about interbreeding or molecular composition was not available. In microorganisms it clearly underestimates real diversity.

OTU Operational taxonomic unit. As the description implies, any pragmatically defined (but objective) way of classifying the individuals into mutually exclusive bins will generate OTUs. For example, those sequences sharing a similarity of the LSU rDNA larger than 97%.

PCR Polymerase chain reaction. A method for amplifying a target piece of DNA producing between thousands and millions of identical copies.

Rank-abundance curve A plot of the number of individuals in each species ordered by their rank, starting with the most abundant species and ending with the most rare.

SSU rDNA The gene in DNA that codes for the ribosomal RNA in the small subunit (SSU) of the ribosome. This is 16S rRNA in prokaryotes and 18S rRNA in eukaryotes.

What is the Rare Biosphere?

Sogin *et al.* (2006) defined the rare biosphere with the following sentences: “The large number of highly diverse, low-abundance OTUs constitutes a ‘rare biosphere’ that is largely unexplored... This ‘rare biosphere’ is very ancient and may represent a nearly inexhaustible source of genomic innovation. Members of the rare biosphere are highly divergent from each other and, at different times in earth’s history, may have had a profound impact on shaping planetary processes.”

The concept is easy to understand by looking at a rank-abundance curve (Figure 1). As stated by Sogin *et al.* (2006): “A relatively small number of different populations dominate all samples, but thousands of low-abundance populations account for most of the observed phylogenetic diversity.” This is the case for most living beings in most ecosystems. What makes the case of microorganisms special is that the “depth” of this rare biosphere is at least one order of magnitude (and likely two or three) larger than that of animals and plants. As a consequence, the difference in abundance between the most abundant and the most rare species ranges several orders of magnitude. This effectively “hides” members of the rare biosphere from their detection with conventional molecular techniques. Hundreds or even thousands of individuals of the more abundant species have to be examined before a single representative of a rare one is encountered. Thanks to current developments in high-throughput sequencing (HTS) technology, exploring this rare biosphere is now beginning to be possible.

In fact, the paper by Sogin *et al.* (2006) not only introduced the term, but also a method to study it based on massive parallel sequencing. The procedure included one

initial polymerase chain reaction (PCR) step to amplify all the small subunit (SSU) rDNA in the sample and then a round of 454-pyrosequencing. The latter technique provides around a million simultaneous sequences from a sample. Since the previous PCR step insured that only SSU rDNA molecules were present, all the sequences obtained in the second step were relevant for the study of diversity. Thus, for the first time, hundreds of thousands of sequences could be analyzed, compared to the few hundreds that were practical with conventional cloning and sequencing. Metagenomics can also provide many sequences and, moreover, without the biases introduced by the PCR step. However, precisely because this PCR step is not there, the sequences obtained correspond to all the genes of all the microorganisms in the sample. As a result, only a very small fraction of the sequences is relevant for diversity studies. Venter *et al.* (2004), for example, obtained over one million genes from the Sargasso Sea, but only about 4000 rDNA molecules. The two approaches are useful for different purposes. The second step, the pyrosequencing, also has potential problems. Particularly, even if sequencing errors are a very small percentage of the total (as is the case), when one has to deal with hundreds of thousands of sequences, there will be a significant number that will be erroneous. Distinguishing between the good and the bad sequences is a delicate methodological issue that has received considerable attention (Huse *et al.*, 2010; Quince *et al.*, 2011, and references therein). For the purpose of the present article, we do not need to worry. It is sufficient to realize that current sequencing technologies provide from one to two orders of magnitude more sequences than previous conventional molecular techniques and this fact now allows the exploration of the rare biosphere.

The Number of Microbial Species

Naturalists, environmentalists, and ecosystem managers like to have a checklist of the species present in a given province, or a given nature reserve, or a national park. These checklists are very useful for decision making. For example, a park with several endangered species present will require a higher priority for conservation efforts than a park where none of the species is in danger. The checklists are also useful for visitors, who can familiarize themselves with the organisms they can expect to find in the park when visiting it. Obviously, checklists are at the base of both conservation biology and ecotourism. In most cases, checklists are available for mammals and birds. In some cases there are checklists also available for amphibians, reptiles, and fishes. Usually, checklists of insects only include butterflies. In some very well-studied environments, there will be a long list of bees, ants, beetles, and all the rest. But, what about the microbes? Is there a checklist of the microbes of any place? Most of the time, managers and environmentalists don't even think about including microbes in the inventory of diversity of a place. But, sometimes, conscientious biologists realize the microbes are missing and then they ask a microbial ecologist the dreadful question: "Do you know how many species of microbes are there in this ecosystem?" The answer, of course, is "no." But the conscientious biologist will not stop there. "This is your chance to make the microbes visible, to put them on a par with the larger animals and plants. Are you going to miss this opportunity?" "Give an educated guess, one hundred? One thousand? A million?"

A substantial part of this paper is a long answer to this question and the reasons why despite microbes making up most (and by most, the author means more than 95%) of the biodiversity on Earth, microbiologists cannot come up with an estimate of the number of species in any single place; much less the number of microbial species on the Planet, particularly the hundreds, or thousands, or perhaps millions that make up the rare biosphere.

The Biological Species Concept and the Phylo-Phenetic Concept in Microorganisms

First of all we should determine what a species is. Despite the fact that there are more than 20 concepts for the definition of species, the most widely used is the biological species concept. Two populations belong to the same species if their members can reproduce sexually and their descendants are fertile. Bacteria, however, do not have sex. They do have several mechanisms to exchange genetic material, but not sex. Therefore, the biological species concept is not applicable to bacteria. The most commonly used definition of a bacterial species is a pragmatic one, the phylo-phenetic species concept: A species is "a monophyletic and genomically coherent cluster of individual organisms that show a high degree of overall similarity in many independent characteristics, and is diagnosable by a discriminative phenotypic property" (Rosselló-Mora and Amann, 2001). The basic requirement to use this concept is to have the bacterium in pure culture, because the definition requires a series of genetic and physiological measurements that can only be done in culture. Once isolated, the taxonomist can determine the sequence of the SSU rDNA, whether the organism is a strict aerobe or whether it can grow by fermentation or not. Moreover, its genome can be sequenced and DNA-DNA hybridization experiments can be carried out to determine the relationship to its closest relatives.

It would be desirable to compare the phylo-phenetic concept with the biological species concept. This would tell us whether we are treating all living beings in a coherent way or whether we have a bias to be splitters in one domain of life while being lumpers in a different domain. Fortunately this can be done, not with bacteria, but with some Protists that do have sex. One particularly good example is that of the diatoms of the genus *Pseudo-nitzschia*. Many diatoms do have plus (+) and minus (−) strains. A+ strain can mate with a − strain of the same species and carry out sexual reproduction, with a mechanism equivalent to that of animals and plants.

Figure 1 (a) Rank-abundance curve for the bacteria in a sample from the Northwestern Mediterranean Sea. The curve plots the number of individuals of each species vs. the rank of that species. In this case, operational taxonomic units (OTUs) are used as proxies for species. The plot follows the convention of showing relative abundance in a log scale in the Y-axis and rank in a linear scale in the X-axis. There is a 4-log difference in the abundance of the most abundant OTU (a SAR11 phylotype, in orange) that accounted for 11% of all the sequences, and one of the least abundant ones such as *Leeuwenhoekiella blandensis* MED217 that was found to comprise only 0.003% of the sequences (in yellow). The former was the most abundant in conventional clone libraries but has not been isolated in pure culture. The latter could be isolated in pure culture but was not found in conventional clone libraries. The 50 most abundant OTUs (blue arrow) made up 75% of all the sequences, but most of the OTUs were very rare. The latter form the rare biosphere. (b) Rank-abundance curves for different microorganisms in samples taken in the Northwestern Mediterranean Sea. The plot retains the conventional log scale for the Y-axis (as in (a)), but shows the X-axis also in a log scale to facilitate comparisons across the whole range of abundances. Tintinnid ciliates and protists were binned into morphospecies using inverted microscopy. Bacteria were binned into OTUs based on 454-pyrosequencing of the V6 region of the SSU rDNA. D5 and D2000 are samples from the surface and the bottom of an open sea station. The total number of taxa (arrows on the X-axis) was 10^1 for Tintinnids (blue arrow), 10^2 for protists (green), and 10^3 for bacteria (at least in the deep sample, brown arrow). Only 10^3 individuals were examined for Tintinnids and, therefore, their curve is truncated for lack of data. However, the same number of individuals (or sequences) was examined for protists and bacteria. Morphospecies, however, are known to lump together many species. Thus, if true species could have been determined for protists, their curve would have been closer to the curves for bacteria. Tintinnid data from Dolan JR and Marrasé C (1995) Planktonic ciliate distribution relative to a deep chlorophyll maximum: Catalan Sea, N.W. Mediterranean, June 1993. *Deco-Sea Research I* 42(11112): 1965–1987; protist data from Margalef R (1969) Estudios sobre la distribución a pequeña escala del plancton marino (in Spanish). *Memorias de la Real Academia de Ciencias y Artes de Barcelona* 60: 1–22; Estrada M (2008) Explorations on phytoplankton diversity. An appreciation of Ramon Margalef's Contributions. In: Valladares F, Camacho A, Elosegui A, et al. (eds.) *Unity in Diversity. Reflections on Ecology after the Legacy of Ramon Margalef*, pp. 191–222. Bilbao: Fundación BBVA, and bacterial data from Pommier T, Neal PR, Gasol JM, Coll-Lladó M, Acinas SG, and Pedrós-Alíó C (2010) Spatial patterns of bacterial richness and evenness in the NW Mediterranean Sea explored by pyrosequencing of the 16S rRNA. *Aquatic Microbial Ecology* 61: 221–233.

The descendants are fertile. The + and – strains of different species cannot have a successful sexual reproduction. This, therefore, fulfills the biological species concept. How does this compare to the phylo-phenetic definition of species in diatoms? Amato *et al.* (2007) studied 95 clones of *Pseudo-nitzschia* isolated from the Bay of Naples. Traditional taxonomy of these diatoms relies on light microscopy. Morphologically, the clones studied fit into two different morphospecies: *Pseudo-nitzschia pseudodelicatissima*-like and *Pseudo-nitzschia delicatissima*-like. To use the phylo-phenetic concept, the researchers analyzed the *rbcl* gene, the large subunit (LSU) rDNA gene, and the interspacer regions (ITS1) and (ITS2). The *rbcl* gene is a functional gene (located in the chloroplast) that codes for the LSU of ribulose biphosphate carboxylase, the central enzyme for carbon fixation in photosynthesis. The LSU rDNA is similar to the commonly used molecular marker for all microorganisms (SSU rDNA). The ITS1 and ITS2 are non-coding regions separating the three ribosomal RNA genes in the RNA operon. Because they do not code for anything, these ITS regions are extremely variable and allow separation of very closely related organisms. In parallel, Amato *et al.* (2007) tried all possible sexual crossings among the different clones. According to the biological species concept there were eight species hidden in the two morphospecies (Figure 2). The ITS regions clustered the clones into the same eight species, while the LSU rDNA produced only seven; that is, two of the species had identical LSU rDNA. Once they had this information, Amato *et al.* (2007) did a careful study of the morphology of

the different species by electron microscopy and, effectively, they could find small, but clear differences among the eight species. This example shows that when it is possible to compare them carefully, the biological species and the phylo-phenetic concepts are quite similar in the delineation of species. It also demonstrates that the rDNA underestimates real diversity.

Pure Cultures Versus Sequences

Thus, if we could isolate in pure culture all the bacteria inhabiting the oceans, we could proceed to define species with the phylo-phenetic concept and come up with an estimate of the total bacterial diversity that could be compared reasonably well with the diversity of animals and plants. Unfortunately, many microorganisms, some would say most, have not been isolated in pure culture. Despite recent efforts to design better culturing techniques, it is estimated that perhaps only 1% of the bacteria in the oceans have been isolated in pure culture. Worst, some of the most abundant bacteria have not been isolated and many of those in pure culture are not abundant in nature. The microbial ecologist, therefore, has to resort to something less desirable, but pragmatic. The choice that has been made is to use the SSU rDNA as a probe for diversity studies. One good thing about this choice is that, as was evidenced in the *Pseudo-nitzschia* example presented above, the biological species concept is more of a splitter than SSU rDNA. If we use SSU rDNA to determine

Figure 2 A comparison of different approaches to determine protist species. The blue rectangle encompasses all the clones that belong to the morphospecies *Pseudo-nitzschia pseudodelicatissima*. The use of LSU rDNA identifies four clusters within this morphospecies (yellow). The use of ITS regions further subdivides one of the clusters in two (green). These finer divisions coincide exactly with the biological species concept tested by crossing + and – clones of each groups of species (red). Only one of the two morphospecies considered by the authors is shown as an example. Reproduced from Amato A, Kooistra WHCF, Levaldi Ghiron JH, Mann DG, Pröschold T, and Montresor M (2007) Reproductive isolation among sympatric cryptic species in marine diatoms. *Protist* 158(2): 193–207, with permission from Elsevier.

species pragmatically, therefore, we will be underestimating the diversity of microorganisms, not overestimating it. Our estimate will be conservative.

Well, then, why don't we just sequence the oceans and count the number of different rDNAs? In fact, this has been attempted several times with different techniques. The first step is to concentrate microbial cells on a filter. Despite the fact that there are almost one million bacterial cells per ml of seawater, in order for the techniques to work, we need to have a certain amount of biomass on a filter. Next, we need to extract the nucleic acids (NAs). The biochemical procedures to do this have been well established for decades. However, some cells will not break up and some others may have their NAs destroyed by the procedure. Therefore, we will have a sample that may be biased with respect to the natural environment. Nevertheless, the resulting NAs will have the DNA and the RNA of most of the microorganisms that were collected on the filter. We need to use a method to select only the NAs of interest, that is, the SSU rDNA. The usual procedure is to use the PCR. Using primers that will match conserved sections of the rDNA, this technique will generate many copies of the rDNAs in the sample. Again, the PCR may introduce some bias: some NAs, by virtue of their secondary structure, may be less efficiently amplified, others may have sequences that do not exactly match the primers, and so on. But we will have a mixture with many copies of the SSU rDNAs of many, probably most, of the members of the original assemblage without any other NAs.

Now we need to separate the molecules corresponding to each living being so that we can sequence them. Usually, this is done constructing a clone library. The amplified SSU rDNAs

are mixed with a culture of *Escherichia coli* cells prepared to take up pieces of DNA. The procedure is done so that most cells will have incorporated only one molecule of DNA from the mixture. When these cells are grown in a Petri dish, each cell will reproduce producing a clone of identical cells, each one carrying one copy of the 16S rDNA of one of the organisms in the sample. Now we can easily sequence this fragment. In principle, if an organism was very abundant in the sample, there should be many clones with its sequence. And the opposite should be true for the rare ones. Thus, despite the biases mentioned above, the clone library will provide an estimate of how many different species were there and an indication of their relative abundances.

The Failure of Conventional Molecular Techniques

So, how many species are there? Using this approach, Hagström *et al.* (2002) sampled several areas of the ocean and constructed clone libraries consisting of around 600 clones each. At the time these were considered to be very large libraries. Comparing the sequences from the different places these authors came up with an estimate of a few thousand species of bacteria for the whole ocean. Unfortunately, this still does not resolve the issue, because there is a question that needs to be answered first: How many clones need to be sequenced to have all the species in a sample? Let us look at the example in Table 1. The table shows the results from a clone library constructed with 18S rDNA from an Antarctic sample, where a total of 67 clones were sequenced (Díez *et al.*, 2001). At the time this was a reasonable number of clones. The most abundant rDNA

Table 1 Distribution of clones in a clone library constructed from a surface sample collected in the Scotia Sea (Antarctica) in January 1998

# clones	Clone name	Closest match (% similarity)	Group
16	ANT37-5	<i>Phaeocystis antarctica</i> (99.8)	Prymnesiophytes
6	ANT12-7		Novel stramenopiles
6	ME1-27	<i>Pelagomonas calceolata</i> (100)	Pelagophytes
5	ANT12-6		Novel stramenopiles
5	ANT12-24		Novel stramenopiles
5	ME1-2	<i>Mantoniella squamata</i> (96.8)	Prasinophytes
3	ANT12-13		Fungi
3	ME1-3	<i>Ostreococcus tauri</i> (94.1)	Prasinophytes
2	ME1-13		Ciliates
2	ANT12-10		Novel stramenopiles
2	ME1-4	<i>Prymnesium patelliferum</i> (94.3)	Prymnesiophytes
1	ANT12-14		Cercomonads
1	ME1-11	<i>Strombidium purpureum</i> (93.3)	Ciliates
1	ANT12-3	<i>Pseudo-nitzschia multiseriata</i> (98.6)	Diatoms
1	ME1-16	<i>Skeletonema costatum</i> (96.8)	Diatoms
1	ANT37-6	<i>Gymnodinium mikimotoi</i> (96.7)	Dinophytes
1	ANT12-4		Glaucocystophytes
1	ANT12-5		Novel stramenopiles
1	ANT12-9		Novel stramenopiles
1	ANT12-8		Novel stramenopiles
1	ME1-24	<i>Hyphochytrium catenoides</i> (90.2)	Novel stramenopiles
1	ANT12-11	<i>Hyphochytrium catenoides</i> (93.7)	Novel stramenopiles
1	ANT12-2	<i>Phaeocystis antarctica</i> (97.6)	Prymnesiophytes

The clones without a closest match are those where the similarity to the closest match was lower than 90%.

Source: Data from Díez B, Pedrós-Alió C, and Massana R (2001) Study of genetic diversity of eukaryotic picoplankton in different oceanic regions by small-subunit rRNA gene cloning and sequencing. *Applied and Environmental Microbiology* 67(7): 2932–2941.

in the sample corresponded to *Phaeocystis antarctica* and the cloned sequence was 99.8% similar to that of the organism known from pure cultures. This was a very logical result, since *Phaeocystis* is known to be a very abundant alga in some Antarctic waters and the high similarity insured that the organism in the sample was essentially the same as the one in culture. Next, there were several organisms found at intermediate abundances (say between six and two clones each), and finally, only one clone was found for the last 12 organisms. The difference in abundance between *Phaeocystis* and these rare organisms was one order of magnitude. Now, what would happen if instead of 67 clones we had sequenced 670? Likely, we would have found 160 clones of *Phaeocystis* and 10 clones of each one of the rare organisms. No doubt we would have found many new organisms represented by only one clone. These new organisms were present in the sample from the beginning, but in concentrations two orders of magnitude lower than *Phaeocystis*. Obviously, the species richness of our library depends on how many clones we obtain and sequence. This is similar to the problem that plant and animal ecologists face with the rare species. Since nobody can count and identify all the individuals in a community, ecologists have resorted to collector curves. These curves show the increase in species as more individuals are identified. Normally, when a sufficient number of individuals have been identified the rate of increase of new species found abates and an asymptote is eventually reached. This is a clear sign that we have a proper estimate of the species richness in our community.

Unfortunately, most of the time this does not happen in the case of microorganisms. The collector curves very rarely reach an asymptote (Figure 3). Why don't the curves for microorganisms behave like those for animals and plants? The reason is sex. Most microorganisms do not need sex for reproduction. As mentioned, bacteria (and archaea) do not have sex, and most known protists can reproduce for long periods of time without sex. Animals and plants, however, need sex to reproduce. This means that individuals from the two sexes have to find each other. When a species becomes rare, the chances of a male and a female meeting decrease and, below certain population abundance, they will not meet and the species will become extinct. A dramatic example of this was the recent extinction of the Po'ouli (*Melamprosops phaeosoma*), a Hawaiian honeycreeper whose last individual died in the hands of conservationists in 2004. The individual had been captured as a last effort to breed the species in captivity. At that time, the wild population consisted of only three birds (a male and two females), but their territories were so far away from each other that they could not possibly meet without human intervention. Unfortunately, the captured bird died and the other two were never seen again (Powell, 2008).

Microorganisms will not have this fate. In principle, a single cell, under appropriate conditions, can reproduce and become several orders of magnitude more abundant in a matter of hours. Thus, the number of rare species in microbial communities can potentially be huge. Think of identifying all the bacteria in 1 ml of seawater. Since there are approximately one million prokaryotic cells in 1 ml of seawater, this would provide one million sequences. For sure there would be several prokaryotic species represented by only one sequence. So, let us sequence all the bacteria in 1 l of seawater. Now we

Figure 3 Collector curves for bacteria in two Northwestern Mediterranean Sea samples, coinciding with those shown in Figure 1(b). Data from Pommier T, Neal PR, Gasol JM, Coll-Lladó M, Acinas SG, and Pedrós-Alió C (2010) Spatial patterns of bacterial richness and evenness in the NW Mediterranean Sea explored by pyrosequencing of the 16S rRNA. *Aquatic Microbial Ecology* 61: 221–233.

would have 100 million sequences and many more species represented by only one clone. What would happen if we could sequence the whole ocean? There are 10^{29} prokaryotic cells in the ocean. To place the magnitude in context, there are only 10^{11} stars in our galaxy or neurons in our brain. How many species can there be in such a huge number of cells?

HTS

It is impractical to sequence more than 1000 clones with conventional techniques, so just to begin to cope with these dimensions requires a different approach: HTS. In the past decade several technologies have been developed that use massive parallelism to obtain hundreds of thousands of sequences simultaneously. Two of the most popular ones are 454-pyrosequencing and Illumina. So, let us see what we get when we increase the number of sequences from a sample by one or two orders of magnitude. Figure 3 shows an example of data obtained by pyrosequencing from the Mediterranean Sea. After examination of 20,000 sequences, the collector curves were not reaching an asymptote. The number of species found was 1577 and, moreover, about 60% of these were represented by only one sequence (Pommier *et al.*, 2010). Obviously, 20,000 sequences are still not enough to saturate the collector curve. We need to increase our resolution at least another order of magnitude or, preferably, two orders of magnitude. Using this approach, Amaral-Zettler *et al.* (2010) estimated that 1 l of seawater must contain about 20,000 bacterial species. However, this cannot be extrapolated to the whole ocean, because the 20,000 species in two different liters of water may share some, many, or perhaps all species. How many species are shared is not known.

Here we need to examine the next characteristic of the rare biosphere: its “depth.” Up to this point, we have established that, because most microorganisms do not need sex to reproduce, they can be extremely rare in a community and yet not become extinct. And we have seen that HTS has confirmed that the number of rare species is very high.

Is Everything Everywhere?

Given that microorganisms are very small and that they are found in very large numbers, it could be expected that they would be easily dispersed worldwide (Finlay, 2002). Thus, all microbial species would arrive at all ecosystems. Once there, they would only be able to grow and become abundant if environmental conditions were adequate. Otherwise, these species coming from far away would remain in very low concentrations, that is, they would be members of the rare biosphere. This, in fact, is what the well-known Baas-Becking expression “everything is everywhere, but the environment selects” tried to capture. For example, bacteria living in the sands of the Sahara desert are taken away by storms and deposited in the Atlantic and the Mediterranean periodically. It is unlikely that these soil bacteria will find conditions favoring their growth in the ocean and, therefore, they will remain in low concentrations. If they are not able to grow, they should eventually disappear because there are several mechanisms that kill bacteria. The question is whether the loss mechanisms are faster or slower than the colonization events. If colonization is faster than losses, all bacteria will be present in all ecosystems in the world. In this case, the rare biosphere in any ecosystem will contain absolutely all the biodiversity on Earth, only many or most of the species will be found in concentrations several orders of magnitude lower than the abundant ones. If the loss mechanisms are faster than colonization, however, the rare biosphere will be different in different parts of the ocean, and not all the species will be present in any one ecosystem.

One interesting property of the rare biosphere is that the main loss mechanisms for bacteria are either not active or reduced. The two most important loss mechanisms are viral lysis and predation by protists. Viruses must find their prey cells by chance, since they only move by Brownian motion. If the concentration of susceptible cells is below a certain threshold, the probability of a virion encountering a susceptible cell is too low to be of any significance. Thus, the species in the rare biosphere are protected from viral attack, because they are found in concentrations that are too low for their viruses to find them. In the case of predation the issue is a bit more complicated. Predators, if not selective, will cull down all bacteria in proportion to their abundance. Therefore, being rare would not be a huge advantage. However, if a bacterium is rare because it cannot grow, most predators will tend to avoid eating it in favor of bigger, more active, cells and being rare will also protect from predation at least partially. Thus, the only loss mechanisms affecting bacteria in the rare biosphere will be starvation and, if they are close to the surface of the ocean, ultraviolet radiation. This means that losses for rare bacteria are very slow and, therefore, the colonization events do not need to be very frequent for the rare biosphere to be very deep.

At the present time we cannot go any further with this reasoning. The available techniques do not allow a sequencing deep enough to see whether all the species on Earth are present in every place or not. But we can certainly state that the number of rare species in any ecosystems will be very large. The experimental evidence available cannot address this question. For example, Galand *et al.* (2009) carried out one of the so far more detailed studies examining several Arctic Ocean samples with 454-pyrosequencing. They divided the OTUs obtained from abundant (those comprising more than 1% of the total) and rare (those accounting for less than 0.01% of the total). They compared community composition among the samples by constructing dendrograms, either with the abundant or with the rare OTUs and they found very similar clustering of samples in the dendrograms. This suggested that the rare biospheres were different in every sample and the results were, thus, against the notion that everything is everywhere. However, the number of sequences examined for every sample was between 10,000 and 30,000, and the collector curve for the samples was not saturated (see their Figure S7). Therefore, the possibility remains that increasing the number of sequences by one (or two, or several...) orders of magnitude would have found all the OTUs in all the samples. The question therefore, is not resolved and, precisely because of this, we cannot say how many species of bacteria are there in the Ocean. The constant improvements in sequencing technology will allow a much better estimate in the near future.

Reasons to be Rare

One more question is why are all these organisms rare? Obviously, all organisms need to have grown in another place or at some time in the past. Otherwise, the loss mechanisms, even if reduced for rare organisms, would eventually cause their extinction. The author will discuss a few possibilities briefly. A more detail discussion of this topic can be found in Pedrós-Alió (2012).

One possibility is that the bacteria currently found in low abundance were abundant in the past but conditions changed and they began to decline in abundance. A typical example would be the seasonal cycle. Some bacteria will find better conditions in spring, for example, after a phytoplankton bloom, they will be very abundant at this time. As the bloom decays, however, conditions become unfavorable for this particular bacterium and its growth rate decreases or even stops. Both viruses and predators will cull down its numbers, until the species crosses the threshold below which it is protected from viruses and predation is reduced. In the absence of growth, this species will in effect have become part of the rare biosphere. The rank-abundance curve shown in Figure 1 is a dynamic curve. At any one time, some of the abundant species are probably on their way down (their rank will eventually move to the right) whereas some rare bacteria that are beginning to find appropriate conditions for growth but are still rare are on their way up (moving their rank towards the left in the curve).

Evidence for this dynamic situation was presented by Jones and Lennon (2010) and Campbell *et al.* (2011). These authors

compared the ranks of bacteria obtained directly from DNA or indirectly from RNA. In the latter case, the ribosomal RNA is retro-transcribed to DNA and, then, the regular sequencing is carried out. The idea behind this approach is that very active bacteria tend to have many ribosomes, while inactive bacteria generally have very few ribosomes. The rank of a given species in the DNA-based estimate indicates the abundance of the species. The RNA-based estimate, in turn, is influenced by the abundance but it will also reflect the activity. Comparing the two estimates, the former authors could find many OTUs that had higher ranks in the RNA-based than in the DNA-based estimates. These OTUs were likely starting to grow and would eventually become abundant members of the community (and eventually increase their rank in the DNA-based estimate as well). However, many OTUs had lower ranks in the RNA-based estimate. These OTUs were likely the ones being culled down by viruses and predators and, eventually, they would find this reflected in lower DNA-based rank. This shifting of OTUs between rare and abundant is probably happening constantly to many of the members of the community. In fact, this is what gives bacterial communities the tremendous capacity to adapt to different situations, from degradation of oil spills to growth in the presence of antibiotics or heavy metals.

The other option is that the rare bacteria are actively growing and abundant at a different place in space and have been transported from elsewhere. The bacteria reaching the sea with Sahara dust storms are an example of this. Another possibility is that of bacteria forming symbiosis with marine animals. These bacteria will be extremely abundant in the specialized organs of the animal, for example, *Vibrio fischerii* is found in abundances of around 10^{11} cells in the light organ of the squid (McFall-Ngai, 2008). The animals culture the bacteria so they grow in the organs during the day, when the squid rests hidden in the sediments. At night the squid rises into the water column to feed and the light emitted by the bacteria helps to camouflage it from both predators and prey. In the morning the squid vents 90% of the cells to avoid becoming overloaded with bacteria. These vented *V. fischerii* are diluted out and transported by mixing and currents and, effectively, become part of the rare biosphere. It is essential for both the bacterium and the squid that they be part of the rare biosphere, because the young squids need to acquire their symbiotic bacteria from the water. If the bacteria were not there, even if in very low concentrations, the new generation of squid would not be able to inoculate their light organs. A similar situation must be true for all the symbiotic bacteria and, since essentially all marine animals have some kind of symbiotic microbiota, these symbiotic bacteria will account for a significant portion of the rare biosphere.

Conclusions and Perspectives

The rare biosphere has proven to be a useful conceptual framework for many different studies of diversity, taxonomy, and ecology. The continuous development in HTS technologies is already providing massive amounts of information. In the next few years, we can expect to be able to estimate, for the

first time, the total number of bacterial taxa in the oceans. Aside from its basic scientific interest, knowledge of these extremely large numbers of bacterial taxa promises access to many genes with interesting potential applications.

Glossary

Archaea One of three domains of life; from the Greek *archaios* (ancient, primitive); prokaryotic cells; membrane lipids predominantly isoprenoid glycerol diethers or diglycerol tetraethers; formerly called archaeobacteria.

Bacteria One of three domains of life; from the Greek *bacterion* (staff, rod); prokaryotic cells; membrane lipids predominantly diacyl glycerol diesters; formerly called eubacteria.

Biomarker A macromolecule unique to a particular organisms or group of organisms such that its detection alone would suggest the presence of the organism or group of organisms.

Chemolithotroph Organism deriving its energy from the oxidation of inorganic compounds.

Eukarya One of three domains of life; from the Greek *eu-* (good, true) and *karion* (nut; refers to the nucleus); eukaryotic cells; cell membrane lipids predominantly glycerol fatty acyl diesters.

Heterotroph Organism deriving its energy from the oxidation of organic compounds.

Hyperthermophiles From the Greek *hyper-* (over), *therme-* (heat), and *philos* (loving); includes organisms that grow best at temperatures warmer than 80 °C.

Photoautotroph Organism that uses light as its source of energy (photosynthesis) and inorganic carbon (CO₂) as its sole carbon source.

Planetesimals Small, solid bodies similar to meteors in composition but revolving in orbit around a central gaseous nucleus, as do planets around the sun.

Small subunit ribosomal RNA RNA (about 1500 bases in prokaryotes) that functions as part of the ribosome and the sequence permits the inference of evolutionary relationships among organisms.

Thermophiles From the Greek *therme-* (heat) and *philos* (loving); includes organisms that grow best at temperatures between 50 ° and 80 °C.

Introduction

At the time when liquid water—a prerequisite for life as we know it—appears in the geological record (3.8 billion years ago), Earth was a hot, anoxic environment and under constant bombardment by meteors, many of which could have virtually vaporized the oceans. Early Earth, therefore, would have been an attractive home to heat-loving thermophiles and their extreme cousins, the hyperthermophiles, where thermophily would have offered a great selective advantage. The geochemical and thermal characteristics of deep-sea hydrothermal vents and terrestrial hot springs are thought to approximate conditions on Earth at the earliest possible time that it could have supported life, providing modern analogs for testing the early evolution of life hypotheses. In addition, the relatively recent use of the evolutionarily conserved molecules such as the small subunit ribosomal RNA (ss rRNA) sequences in phylogenetic analyses of all life has placed the thermophiles closest to the root of the universal tree of life (Figure 1). On this tree, hyperthermophiles decidedly monopolize the lowest and shortest branches, suggesting that they may be related to the earliest microbes to inhabit Earth. However, the proposal that thermophiles may have originated early in Earth's history is much debated. Therefore, this article also considers alternative scenarios for the origins of thermophiles.

Thermophiles and Hyperthermophiles Defined

All life can be placed in one of the three domains of life: the Archaea, Bacteria, or Eukarya. Archaea and Bacteria are prokaryotes, and the Eukarya are eukaryotes. However, phylogenetically, the Archaea are as different from the Bacteria as the Bacteria are from the Eukarya. Thermophiles are found in all domains as multicellular and unicellular organisms, such as fungi, algae, cyanobacteria, and protozoa, and they grow best at temperatures higher than 45 °C. In contrast, the extreme thermophiles, or hyperthermophiles, grow best at temperatures higher than 80 °C and are almost exclusively restricted to the Archaea, with only two hyperthermophilic orders in the Bacteria, namely, the Thermotogales and Aquificales. Commonly, thermophiles and hyperthermophiles are found associated with deep-sea and terrestrial hydrothermal vents. Thermophiles have also been obtained from deep (up to 3500 m), hot, subterranean areas, Jurassic oil-bearing sandstone and limestone formations, and suitable manmade environments such as smoldering coal refuse piles, coal-containing uranium mines, and boiling waste-waters from geothermal power plants.

Ecological Niche and Metabolic Diversity of Hyperthermophiles

Deep-sea hydrothermal and terrestrial hydrothermal vents form primarily as the result of plate tectonics, either as a result

Figure 1 Rooted phylogenetic tree based on the small subunit rRNA molecule. The tree is not drawn to scale.

Figure 2 Sampling a deep-sea hydrothermal vent chimney from the eastern Pacific Ocean. The porous sulfide chimney structures can reach several meters high and are ideal habitats for hyperthermophiles.

Figure 3 Moose Pool, Yellowstone National Park, Wyoming. This acidic thermal spring contains elemental sulfur that accumulates on the gas bubbles (see inset). The archeon *Sulfolobus acidocaldarius* was isolated from this spring in the late 1960s by Thomas Brock.

of seafloor spreading or as a tectonic plate moves across a hot spot. In both scenarios, fissures and faulting occur in the earth's crust, permitting water (seawater, groundwater, or rainwater) to percolate downward. As the fluid moves through the earth's crust and approaches the magma chamber, the fluid heats and reacts with the surrounding rocks, adding some minerals and gases (e.g., iron, manganese, carbon dioxide, hydrogen, and hydrogen sulfide) and removing others (e.g., sulfate and magnesium in seawater). The fluid is finally forced back to the surface as a highly altered hot fluid, its chemistry representing a history of its travels through the earth's crust. At deep-sea hydrothermal vents, this fluid can reach temperatures of 400 °C, remaining in a liquid state due to the hydrostatic pressures at these depths (> 2000 m). It rapidly mixes with cold, oxygenated water, and the minerals rapidly precipitate, giving the fluid a smoky appearance (Figure 2). These vents are aptly named "black smokers." As the minerals precipitate they create porous sulfide-mineral structures called

"chimneys." At terrestrial hot springs, the fluid may be ejected forcefully as a geyser or simply bubble into a thermal spring or mudpot (Figure 3).

The high temperatures and unusual geochemical characteristics of deep-sea and terrestrial hydrothermal vents create ecological niches that are exploited by hyperthermophilic Bacteria and Archaea. The geochemical milieu provides different energy sources (electron donors) and carbon dioxide for a chemolithotrophic existence. The porous chimney structures provide temperature gradients along which thermophiles can situate themselves, and thermal springs create temperature gradients as the fluid moves away from the source. Comparable to photoautotrophs that harvest light energy to fix inorganic carbon, these chemolithotrophs harvest inorganic chemical energy to fix inorganic carbon. It has been calculated that the mixing of superheated thermal fluids at deep-sea vents with cold, oxygenated seawater causes a significant geochemical disequilibrium, significant enough to lower the

Gibbs free energy and help drive biologically mediated redox reactions (Shock, 1996). The food chain does not stop there, though. Many thermophiles are heterotrophs, consuming organic carbon produced from biological activity. Additionally, at terrestrial vents, due to the available light energy, the springs are often colonized by a rich diversity of thermophilic phototrophs, including the cyanobacteria, which are oxygenic phototrophs that use water as the reductant and evolving oxygen in the process. Anoxygenic phototrophs are also found at terrestrial vents, primarily using the readily available hydrogen sulfide as the reductant in photosynthesis, releasing elemental sulfur in the process. Both of these types of phototrophs are part of a complex community with heterotrophs, and together they form thick green, purple, and orange microbial mats typical of many terrestrial thermal areas throughout the world.

The majority of hyperthermophiles are anaerobes, with a few exceptions that are microaerophilic, requiring low oxygen concentrations for growth. In contrast, aerobiosis is more common among the thermophiles because oxygen dissolves more readily in the lower temperatures of the cooler thermal springs. The thermophiles that have been isolated from deep-sea vents generally grow at pH values near neutrality. However, thermophiles from terrestrial hot springs have been grown at pH values from 1 to 10.

Although the highest temperature for life has not been determined, it has been suggested that 150 °C may represent that threshold. In contrast, the lower temperature limit for most hyperthermophiles is 60 °C, a temperature fatally hot for most other organisms. Even 90 °C is too low for one of the more extreme hyperthermophiles, *Pyrolobus fumarii*, which has a maximum temperature for growth of 113 °C. However, for these thermophiles, the inability to grow does not result in death; they are capable of entering a dormant state when exposed to cold conditions and will thrive again when returned to favorable temperatures. Thermophiles are therefore very well suited to the deep-sea hydrothermal vent environment, in which the hot fluids are continually being mixed with cold, oxygenated seawater.

Molecular Mechanisms for Thermophily

On a molecular level, thermophily is accomplished in many ways, contributing together to overall stability and success of life at high temperatures. In general, the amino acid composition of hyperthermophilic enzymes is surprisingly similar to that of homologous mesophilic enzymes. Because of the amino acid sequence similarity, it has been proposed that heat resistance is explained, instead, by the manner in which the polypeptide chains are folded on themselves, forming their tertiary conformational stability. It is a polypeptide's three-dimensional or tertiary shape in critical locations on the polymer that permits an enzyme to function. Proteins do not spontaneously fold into their active form after synthesis. Instead, many require the assistance of molecular chaperones for proper folding. A specialized form of molecular chaperone, called a thermosome, is of particular importance to hyperthermophiles because it assists proteins in refolding correctly after denaturation due to heat exposure. Also called heat shock

proteins, thermosomes effectively increase heat tolerance of organisms so they can function at higher temperatures. For instance, at 108 °C, approximately 80% of the protein of *Pyrodicticum occultum* consists of a heat-induced thermosome, allowing it to survive 1 h of autoclaving at 121 °C (Stetter, 1998).

Additional thermal resistance of DNA is conferred by the presence of DNA topoisomerases and histones and, to a lesser extent, by the base composition of the genome. All hyperthermophiles known to date have been shown to possess reverse gyrase, a unique type I DNA topoisomerase that causes stabilizing, positive supertwists in the DNA helix. Additionally, archaeal (but not bacterial) hyperthermophiles possess histones which significantly increase the temperature at which DNA denatures.

Because an increased guanine + cytosine (G + C) nucleic acid content increases the melting temperature of DNA, one would predict that hyperthermophiles have a higher G + C content in their genomes. In many cases, the opposite is true. However, analysis of the genome reveals that certain genes essential to survival, such as the ss rRNA gene, have higher G + C contents.

The presence of ethers instead of esters in cellular membranes also contributes to the stability of hyperthermophiles at high temperatures. Cell membranes of Bacteria and Archaea are generally distinguished by the presence of glycerol-linked ether lipid moieties in Archaea and ester lipid moieties in Bacteria. An exception to this rule is the presence of a glycerol ether lipid in *Thermotoga maritima*, one of the few bacterial hyperthermophiles. The presence of the ether lipids probably increases stability of cellular membranes against hydrolysis at high temperatures. Membranes of the archaeal hyperthermophiles contain lipids derived from diethers or tetraethers and are highly resistant against hydrolysis at high temperatures.

Origin of Thermophiles: Fossil Record and Universal Phylogenetic Tree

Were thermophiles the original ancestors to all life? Much of the debate about origins of life and early evolution of life on Earth centers on this question. Is thermophily an acquired feature derived from adaptation? As more information accumulates, the resolution of these questions becomes less clear. However, many different scenarios are emerging based on fossil record analyses, RNA and protein phylogenies, and our understanding of the conditions that prevailed on early Earth.

Early Earth and Its Hyperthermophilic Niche

Perhaps the most compelling evidence supporting the proposal that hyperthermophiles are living fossils of the first life that arose on Earth is that modern ecological niches of hyperthermophiles fit our current view of the conditions on primitive Earth, which was anoxic, hot, and volcanically active. During its first half billion years of existence (4.6–4.0 billion years ago), the temperature of the surface of Earth probably exceeded 100 °C. From recent studies of ancient sedimentary rocks of the Isua formation in Greenland, traces of biologically

produced carbon were detected, suggesting that the invention of life had already taken place 3800 billion years ago. Thus, sometime prior to 3800 billion years ago, it is likely that the first living organisms appeared at a time when Earth, although cooling, was much hotter than it is now, and all the essential geochemical energy sources were present for a chemolithotrophic and thermophilic existence. Heat-tolerant organisms such as hyperthermophiles would have been at a distinct advantage over heat-sensitive organisms.

In addition to the generally hot and anoxic conditions on early Earth, the bombardment of early Earth by meteors may have caused a bottleneck event that favored survival of hyperthermophilic organisms. An examination of the impact craters on Earth's geologically inactive moon strongly suggests that the earth was heavily bombarded by meteors from its formation 4.6 billion years ago until about 3800 billion years ago. A large meteor impact, of which there were many, would have caused intense local heat and sent sufficient debris into the atmosphere to cause global cooling and a reduction in light intensity, detrimentally impacting photo-synthesizing organisms. There is also evidence of extremely large meteor impacts that would have generated enough energy to heat the earth's surface to 2000 K and virtually vaporize the world's oceans. In either scenario, hyperthermophiles would have been uniquely adapted to survive. They could have tolerated lower light levels because many are chemolithotrophs, making a living independent of photosynthesis. Any life adapted to live near ocean-floor volcanic centers would have had the greatest chance of surviving one of these ocean-evaporating events.

The Fossil Record

Additional evidence for early ancestors of microbial life can be found in the rock record. Rocks older than 3500 billion years are highly metamorphosed and deformed, precluding the preservation of morphological fossils. However, the 3800-billion-year-old Isua rocks from Greenland, mentioned previously, offer indirect evidence that life existed earlier than 3500 billion years ago. These sedimentary rock formations are associated with liquid water, a prerequisite for life as we know it. The rocks contain geochemical evidence of past biotic activity preserved within the minerals. Grains of apatite (calcium phosphate) contain a significant portion of carbonaceous inclusions that are isotopically "light," suggesting biological activity. Microorganisms preferentially incorporate the lighter carbon-12 isotope over the carbon-13 isotope when inorganic carbon is fixed into organic carbon using the enzyme ribulose biphosphate carboxylase/oxygenase (Rubisco). This isotopic evidence suggests these putative life-forms were carbon-fixing chemolithotrophs or phototrophs and not heterotrophs.

Three hundred million years later, the first microfossils appear in rocks (about 3500 billion years old) from Western Australia and South Africa. The fossils are simple rod-shaped and filamentous bacteria, indistinguishable morphologically from any similar-shaped bacteria today. Many are reminiscent of photosynthetic bacteria, such as modern cyanobacteria. However, there is some doubt that much oxygen evolved from photosynthesis into early Earth's atmosphere. Isotopic

signatures associated with these fossils do suggest a lighter carbon preference, similar to that observed in the 3800-billion-year-old rocks. Were these first fossils perhaps thermophiles? Unless we are able to identify specific thermophilic biomarkers in these fossils, we may never know the answer.

The Molecular Fossils

Although they are not a substitute for the existence of microfossils, evolutionarily conserved macromolecules within living organisms function as "molecular fossils," permitting an inference of relatedness to other organisms and of evolutionary distance from a hypothetical common ancestor. Carl Woese's pioneering work with the ss rRNA molecule (16S rRNA in prokaryotes) led to the generation of the universal phylogenetic tree (**Figure 1**), in which life falls within three domains: the Archaea, Bacteria, and Eukarya. The suitability of ss rRNA as the macromolecule for evolutionary comparisons is based on several critical reasons. The ss rRNA exists in every living organism, its function in every living organism is constant, it is an ancient molecule (assuming protein synthesis was necessary in the earliest of life), it has undergone only moderate changes in nucleic acid sequence when compared between diverse biological domains, and the size of the molecule is large enough to contain considerable information but small enough to be manageable.

Molecular Phylogenies

The relatedness of organisms to each other as suggested by the universal phylogenetic tree is markedly different than the previously proposed phylogenies. Most notably, the three domains of biological life (the Bacteria, Archaea, and Eukarya) replace the five kingdoms (animals, plants, fungi, protista, and monera). The Eukarya domain includes the multicellular animals, plants, fungi, and protista. Distributed throughout the Bacteria and Archaea are the unicellular prokaryotes. Using alternative markers, such as 23S rRNA, RNA polymerase, elongation factor Tu, F_1F_0 ATPase β -subunit, RecA protein, and HSP60 heat shock protein, reveals general agreement with the major lineages in the ss rRNA tree. However, some discrepancies are evident.

One can root the ss rRNA tree by comparing it with a paralogous marker that arose from gene duplications (such as EF-Tu or ATPase) prior to the diversification of the three primary domains. This rooted tree reveals that all hyperthermophiles, whether bacterial or archaeal, comprise the deepest and earliest lineages within the tree (**Figure 1**). In other words, they may be the closest living relatives to a common universal ancestor. However, mutational rates of ss rRNA and their associated base sequence changes are not consistent enough through time nor within lineages to assign a specific date to branching events, and so one cannot assign a clock to this tree. Nonetheless, the shorter branches leading to the hyperthermophiles indicate a slower evolutionary rate, whereas the longer branches leading to their mesophilic relatives suggest a faster evolutionary rate. It is possible that the hyperthermophiles have short lineages because they are so highly adapted to their ecological niche that they have no need for further adaptation. It is also possible that certain evolutionary

constraints are imposed on thermophiles due to the extreme selectivity of the high-temperature environment. Nevertheless, the placement of thermophiles at the base of the universal phylogenetic tree strongly suggests that they are most closely related to the common ancestor of all life. In this sense, they are not unlike other “living fossils,” or organisms whose morphology has changed very little based on comparisons of modern and ancient fossilized specimens, such as horseshoe crabs, club mosses, *Welwitschia*, and *Ginkgo bilboa*.

Although hyperthermophiles may be most closely related to the universal ancestor of all life, their metabolic machinery is anything but primitive. Viewed independently of the rooted ss rRNA universal phylogenetic tree, their heat-tolerant adaptations appear sophisticated or even highly evolved. If an analysis of another universal and highly conserved macromolecule placed hyperthermophiles away from the root of its phylogenetic tree, it would severely shake the topology of the phylogenetic tree discussed previously. A phylogenetic analysis of the conserved DNA-directed RNA polymerase has done just that (Klenk *et al.*, 1999). Although overall the RNA polymerase-based phylogeny corresponds very well with the ss rRNA-based phylogeny, the positions of the hyperthermophilic bacteria *A. pyrophilus* and *Thermotoga maritima* are in the middle of the RNA polymerase tree instead of in the most deeply rooted branch in the Bacteria as suggested by ss rRNA phylogeny. Other examples also exist in which the ss rRNA tree does not quite hold true. Additional analyses of universal and highly conserved macromolecules such as DNA-directed RNA polymerases or whole genomes may one day provide a comprehensive universal phylogenetic tree that may or may not place hyperthermophiles near its root.

The debate continues, and evidence against an early origin of thermophily accumulates. If mesophily preceded thermophily, then versions of heat-tolerant mechanisms that characterize hyperthermophiles would have evolved first in mesophiles and been exploited by hyperthermophiles to open up new ecological niches. Structural analysis of reverse gyrase and *Taq* polymerase support such a proposal, suggesting they evolved from mesophilic ancestors (Forterre, 1996). Additionally, the lipid moieties in hyperthermophilic Bacteria are not homologs of the lipid moieties in hyperthermophilic Archaea. Instead, they are analogs with opposite stereochemistry, suggesting the ether-based lipid moiety feature evolved independently in the Bacteria and Archaea instead of from a common ancestor (Forterre, 1996).

Lateral Gene Transfer and the Genetic Annealing Model

Lateral (horizontal) gene transfer and variable rates of evolution and mutation may have played a significant role in the evolution of life and may offer an explanation for the confusing results of the analyses of non-ss rRNA molecules (Woese, 1998; Doolittle, 1999). Lateral gene transfer refers to the exchange of genetic material from one organism to another. It is contrasted against vertical gene transfer, in which genetic information is passed vertically from parent to offspring. Bacteria and Archaea, which as a general rule have simpler cell designs, exhibit considerable horizontal gene transfer. In contrast, the Eukarya, which contain highly evolved cell designs, generally do not engage in horizontal gene transfer. Woese proposed in his “genetic annealing

model” that the universal ancestor was not a discrete entity but rather a diverse community of primitive cells that evolved as a unit, engaging in horizontal gene transfer on a scale even greater than that occurring in Bacteria and Archaea today and developing into three different communities, which in turn gave rise to the three primary lines of descent as defined by the ss rRNA tree (Woese, 1998).

The ss rRNA universal tree, then, is not a conventional organismal phylogenetic tree but rather a history of the evolution of central components of the ribosome, with the deeply rooted branches of the universal tree representing a “gene tree” and not an “organismal tree.” In other words, by the time the three primary lines of descent emerged, and the tree started to take form, self-replicating organisms had not yet taken form. Instead, “life,” with its associated exchange of genetic information, existed in communal entities by way of lateral gene transfer. Additional cell complexity and function needed to evolve before there was life as we envision it today. Nonetheless, these communal entities could have evolved in the conditions on early Earth.

Theories of the Origin of Life

Theories of the origin of life are highly debated. Did life originate here on Earth, or did it develop on another planet, such as Mars, which shared similar planetary conditions 4.0 billion years ago? Did life originate in environments analogous to deep-sea hydrothermal vents, or did the first biological molecules form as a result of the reaction of electrical discharges within a prebiotic soup of chemicals? Closely tied to much of this debate are models pertaining to early Earth’s atmosphere and the possible energy carbon sources (organic and inorganic). Given that this article deals with the origins of thermophiles, we focus our discussion on a possible high-temperature origin of life, highlighting some arguments that do not support this hypothesis.

In light of Earth’s hot, reduced, and anoxic origins, it has been proposed that life may have arisen in environments very similar to present-day deep-sea hydrothermal vents. Here, life could take refuge and survive the planetesimal bombardment of early Earth in an environment rich in redox energy and inorganic carbon. The first biological entities could evolve rapidly as anaerobic, hyperthermophilic chemolithotrophs. The rapid mixing of superheated hydrothermal fluid, rich in reduced minerals, with cold oxygenated sulfate-rich seawater at deep-sea hydrothermal vents creates thermodynamic disequilibrium conditions that favor the production of organic molecules (Shock, 1996). The abundance of charged minerals associated with deep-sea vents led to the proposal by Gunter Wächtershäuser that the original source of reducing power for carbon fixation (and therefore a chemolithotrophic origin of life) may have come from exergonic “pyrite-pulled reactions”—the oxidative formation of pyrite (FeS_2) from ferrous sulfide (FeS) and hydrogen sulfide (H_2S or SH^-). Charged surfaces such as pyrite would attract and bind any negatively charged molecule in solution, such as carbonate, phosphate, and sulfide. These molecules would be maintained in sufficient proximity for subsequent metabolic interactions by “surface bonding” or anionic bonding to the positively

charged pyrite surface, resulting in the formation of the first biomolecules on a charged surface. Many are skeptical of these high-temperature scenarios for the origin of life, offering evidence that many of the biomolecules of life, such as RNA, are not stable at high temperature and therefore would not support the proposal that RNA arose prior to DNA in an early RNA world (Miller and Bada, 1988). Furthermore, others have generated models to show that the ancestral rRNA would have a moderate G + C content, contrary to all thermophilic rRNAs which are generally rich in G + C contents (Galtier *et al.*, 1999).

The “panspermia” hypothesis offers another scenario for the origin of life. It holds that life originated elsewhere in the galaxy and that microorganisms were propelled through space to Earth or, alternatively, that exogenous organic carbon arriving on planetesimals fueled a heterotrophic origin of life on Earth. Chyba and Sagan (1992) estimate that approximately 4 billion years ago about 100,000,000 kg/year of organic carbon was delivered by interplanetary dust particles, and about 10,000,000,000 kg/year of organic carbon was produced by postimpact plumes caused by meteor, asteroid, and comet bombardment. From what is known about the hostile environment on early Earth and the timing of the appearance of the first microfossils, life became considerably complex within a relatively short period of time. Therefore, life either evolved very rapidly after its inception or, consistent with the panspermia hypothesis, it was raining down on Earth from elsewhere in the galaxy. Because the panspermia hypothesis involves high temperatures as particles enter the earth’s galaxy, it embraces, at the very least, a thermotolerant origin of life.

Conclusion

Morphological features of early microfossils generally offer little information about their relatedness to extant microbes. Consequently, microbiologists have come to rely on the molecular record to define phylogenetic relationships and infer the history of microorganisms. The absence of a good microbial fossil record prevents the assignment of a time line on the molecular record. The ss rRNA universal phylogenetic tree places hyperthermophiles in the deepest and shortest branches of the tree, implying that they are the closest living relative to the common universal ancestor of life. However, as we sequence more microbial genomes and create detailed

phylogenies from other molecules, the situation becomes increasingly confusing, with lateral gene transfer perhaps “muddying” the phylogenetic record. However, high-temperature conditions that prevailed on early Earth and its subsequent cooling favor the likelihood that at some time during Earth’s early history thermophiles took advantage of the geochemical energy supplied by the hydrothermal fluid and evolved into the highly adapted chemolithotrophic and heterotrophic life that is found at high temperatures.

Glossary

Aeolianites Wind-deposited sediments.

Aphyllous Leafless.

CAM metabolism Crassulacean acid metabolism is a carbon uptake system utilized by many succulent plants; these plants fix carbon dioxide during the night when evapotranspiration is relatively low, storing it as organic acids. The stored CO₂ is released during the day and refixed in the typical light reactions of photosynthesis, thereby increasing water use efficiency.

Drought-deciduous Descriptive of plant species that lose their leaves during the dry season as soil moisture becomes limited.

Edaphic Related to or caused by particular soil conditions, as of texture or drainage, rather than by physiographic or climatic factors.

Fynbos Evergreen sclerophyll shrubland dominating the Cape Region of South Africa.

Geophytes Plant with succulent storage tissues such as bulbs, corms, or rhizomes.

Inselberg Isolated mountain that stands above lowland plains below.

Orthophyllous Pollinated by birds.

Petaloid Describing flowers with petals present, and typically showy.

Succulent Having fleshy tissues that store moisture.

Introduction

The Succulent Karoo comprises an area of approximately 103,000 km² stretching down the Atlantic coast of south-western Namibia and South Africa, as well as in dry intermontane valleys and basins within the Cape fynbos biome (Figure 1). This desert area is characterized by a dominance of winter rainfall and shows strong floristic affiliation with the Cape Floristic Region such that most of the area has been included in a Greater Cape Floristic Region (Born *et al.*, 2007). Of special note is the fact that the Succulent Karoo is one of only two biodiversity hotspots that are entirely arid, with the other being the newly recognized Horn of Africa hotspot (Mittermeier *et al.*, 2005).

The Succulent Karoo is commonly divided into two broad components (Jürgens, 1991). The first, Namaqualand-Namib, extends along the west coast of South Africa and southern Namibia. It is a winter-rainfall desert (30–300 mm year⁻¹) with a mild climate moderated by cold Atlantic Ocean currents. The second zone, the Southern Karoo, has a more interior position in elevated intermontane valleys and basins, and thus experiences more extremes of temperature variation than the Namaqualand region (Desmet and Cowling, 1999b). It has a major peak of rainfall in spring and a second peak in autumn, although summers are invariably dry and appreciable winter rain does fall. Annual rainfall ranges from 180 to 350 mm.

The Succulent Karoo is exceptional among the world's desert biomes because of its spectacular diversity of plant species (Cowling *et al.*, 1998; Cowling and Pierce, 1999). The most remarkable component of this diversity lies with succulent plant species, which occur here with richness unparalleled to any other region (van Jaarsveld, 1987). It is this dominance of succulent-leaved plant species that gives rise to the name, Succulent Karoo, in contrast to the larger Nama Karoo biome of South Africa (Cowling *et al.*, 1999). Although the Succulent Karoo and summer-rainfall Nama

Karoo biomes were once lumped together as a warm desert unit of southern Africa with subtropical affinities, the winter-rainfall region has been shown to have strong affinities to the Cape Floristic Region, whereas the Nama Karoo retains subtropical African affinities (Born *et al.*, 2007; Verboom *et al.*, 2008).

The rich biodiversity of the Succulent Karoo is due in large part to an extensive and complex array of subtle biotic changes, derived from topographic, edaphic, and climatic diversity in the biome's landscape (Cowling *et al.*, 2009; Linder, 2008). This landscape lacks high mountains but varies from young coastal dunes across older dune surfaces to upland areas of granitic ranges in Namaqualand, and interior valleys. Many species are extreme habitat specialists with highly limited ranges. Local endemism (i.e., the restriction of species to extremely small ranges of <50 km²) is most pronounced among small Mesembryanthemaceae and other succulents, as well as in geophytes (Desmet and Cowling, 1999a). Similar patterns of compositional change along gradients have been observed for certain groups of invertebrates (Colville *et al.*, 2002).

Dwarf shrublands dominated by low shrubs and subshrubs with evergreen succulent leaves are found throughout the Succulent Karoo and represent the characteristic plant cover (Cowling *et al.*, 1994, 1999). These drought-adapted plants have fleshy leaves or stems for water storage. In the Succulent Karoo, there are approximately 1700 species of leaf succulents, and this dominance is unique among the world's deserts (Cowling *et al.*, 1998, 1999). The recent (Plio-Pleistocene) and explosive diversification of the Mesembryanthemaceae, the largest group, has been described as an event unrivaled among flowering plants (Klak *et al.*, 2004). There are 108 genera and 1132 species reported for this family in the Succulent Karoo (Table 1). Stem succulents are also found here (around 140 species), as are seasonal bulbs and annuals that display magnificent spring blooms in the open spaces between the shrubs, particularly during the spring in Namaqualand (Cowling and Pierce, 1999).

Family	Genera	Species
Mesembryanthemaceae	108	1132
Asteraceae	108	777
Iridaceae	29	408
Scrophulariaceae	39	349
Fabaceae	57	315
Poaceae	84	297
Crassulaceae	5	202
Hyacinthaceae	22	172
Asphodelaceae	8	149
Euphorbiaceae	13	140
Total		3941

Bioregions

Twelve geographic bioregions have been identified within the Succulent Karoo (Figure 1), reflecting geomorphological variation, floristic affinities, and patterns of endemism (Hilton-Taylor, 1996). Ten of these lie in the Namaqualand-Namibian area of the Succulent Karoo, whereas two others form the Southern Karoo area. The Southern Namib Desert encompasses the northern extent of the Succulent Karoo,

largely comprised by the Sperrgebiet in southwestern Namibia and the northwestern South African coast from Port Nolloth to Alexander Bay. The Orange River, the largest river in southern Africa, reaches the coast in this region and forms the boundary between South Africa and Namibia. Diamond mining concessions for this area date back a century, and have restricted public and scientific access. Although mining activities have sharply transformed a narrow belt along the coast (Desmet and Cowling, 1999a), much of the remainder of the area is in pristine condition. A notable site within this area is the fog flora of lichens that completely dominates an area of the coast between Port Nolloth and Alexander Bay. There are 776 plant species reported for the Sperrgebiet, with a third of these endemic (Burke, 2004).

The Gariep Center, which includes upland areas of southwestern Namibia and the greater Richtersveld area, has the richest flora of succulent plants in the world. This region contains an estimated 2700 plant species, with leaf and stem succulents as the overwhelming majority of the flora (van Wyck and Smith, 2001). The approximately 20% of these species that are endemic include many charismatic succulents with highly restricted ranges. The Richtersveld National Park, leased to the South African National Parks by the indigenous local population, protects much of the rugged mountainous portions of this bioregion, and is home to diverse wildlife.

The Namaqua Rocky Hills comprise the largely granitic uplands of central Namaqualand, south of the Greater Richtersveld bioregion. The Namaqua Rocky Hills are famous for their spectacular displays of spring wildflowers, and their remarkable diversity and endemism of geophytes (van Rooyen *et al.*, 1990). Agriculture and heavy grazing, the latter particularly on communal lands, have transformed much of the level terrain within this bioregion (Hoffman and Rohde, 2007; Thompson *et al.*, 2009). The recently established Namaqua National Park is protecting a large part of this region. The Kamiesberg Mountains rise to 1700 m elevation within the Namaqua Rocky Hills, and this elevation provides sufficient rainfall to support patches of fynbos vegetation. The Kamiesberg supports a rich flora of approximately 1000 species, including 80 endemics, most of which are geophytes (van Wyck and Smith, 2001).

The Sandveld comprises a long and narrow belt of the Namaqualand coast dominated by geologically young sandy soils, mostly alkaline but also acid aeolianites. The vegetation is distinct structurally and floristically and gradually grades southward into the coastal thickets and fynbos of the Cape Floristic Region.

The Vanrhynsdorp Center is largely composed of the Knersvlakte, a broad dry plain of approximately 5200 km² bounded on the east by the Bokkeveld Mountains. Extensive plains covered by quartz pebbles occur across this bioregion, a consequence of Pliocene uplift and subsequent erosion of quartz veins. The Knersvlakte is rich in plant diversity, despite its barren appearance, with dwarf succulents scattered in huge densities among the quartz pebbles of its plains (Schmiedel and Jürgens, 1999). A flora of 1324 species is reported for this bioregion; some 15% of these are endemic. South of the Vanrhynsdorp Center lies the Bokkeveld/Olifants River/Biedou bioregion, which forms a transition to the Cape Region communities to the south.

The Western Mountain Karoo occupies high country along the Great Escarpment, a feature that separates the coastal and upland plateaus. Frost is common during the winter months and succulent cover is much sparser than elsewhere in the Succulent Karoo. This bioregion harbors approximately 2500 species, 10% of which are endemic (van Wyck and Smith, 2001). Most of the endemics are geophytes. The Tanqua Karoo occupies a very arid basin that lies between the rain-trapping Cape Fold Mountains to the west, and the Great Escarpment (Western Mountain Karoo) to the east. Owing to the low rainfall ($> 20 \text{ mm year}^{-1}$ falls in the center of the basin), vegetation cover is sparse. However, the area does support a surprisingly rich but poorly explored flora.

The final two bioregions of the Succulent Karoo lie within the Southern Karoo bioregion. These regions experience a very different climate regime to the Namaqualand region because of their location away from the influence of the cold Atlantic Ocean. Summer temperatures regularly reach 40°C , and summer storms penetrate to this region from the warm Indian Ocean to the south, allowing for a biseasonal pattern of rainfall. Nonetheless, mean annual rainfall is relatively reliable – at least by global standards – but less so than for Namaqualand.

The Worcester/Robertson Karoo bioregion lies along the Central Breede River Valley in a rainshadow created by the surrounding Cape Fold Mountains. The bioregion has a flora of 1500 species of which about 8% are endemic; some three quarters of the endemics are succulents (van Wyck and Smith, 2001). Extensive irrigated agriculture and vineyards have transformed much of this area, although pristine patches of landscape remain. The final bioregion, the Little Karoo, comprises a dissected basin lying between the Langeberg and Swartberg Cape Fold Mountains. The flora comprises more than 2500 species of which about 10% are endemic; succulents comprise about one quarter of the endemics (van Wyck and Smith, 2001; Vlok and Schutte-Vlok, 2010). Many of the succulent endemics grow on quartz fields similar to those of the Knersvlakte, described above (Schmiedel and Jürgens, 1999). Extensive areas of this bioregion have been heavily impacted by ostrich farming.

Biodiversity

Plants

For an arid biome, the Succulent Karoo has extraordinarily high plant diversity, including the richest succulent flora in the world (Hilton-Taylor, 1996; Cowling *et al.*, 1998). The size of the flora is estimated at 6356 species, including floristically related communities present on the Bushmanland inselbergs lying in the Nama Karoo biome to the east of the Gariep bioregion, with about 40% of these endemic. Many of these are point endemics, confined to a single habitat that covers a very small area. Approximately 100 genera are endemic to the Succulent Karoo, most of which are succulents (van Wyck and Smith, 2001). The Mesembryanthemaceae, considered here as a segregate family from the Aizoaceae, exhibits a remarkable degree of biodiversity in the Succulent Karoo, with 108 genera and 1132 species. This total for the Mesembryanthemaceae

comprises about 18% of the flora in this single family. The largest 10 families make up more than 60% of the total vascular plant flora. The Asteraceae is the second largest family, making the Succulent Karoo of global significance for the evolution of this family. Three families of geophytes are included in the 10 largest groups present in the Succulent Karoo. These are the Iridaceae, the Hyacinthaceae, and the Asphodelaceae.

Notable plant species found in this hotspot include the botterboom (*Tylecodon paniculatus*), a stem succulent that has glossy leaves in winter and red flowers in summer, and the halfmens (*Pachypodium namaquanum*), a strange stem succulent endemic to the Richtersveld that can grow up to 4 m tall. Clusters of halfmens stems tend to face toward the north, giving the appearance of groups of people gazing northward. The terminal crowns of leaves, which resemble hairy human heads, enhance the impression. The scientific explanation for this unusual orientation is that the plants, which grow on shaded slopes, lean northward in order to ensure that their leaves and developing flowerheads, produced during the cool, foggy winter months, are maximally exposed to solar radiation (Rundel *et al.*, 1995).

Vertebrates

Vertebrate diversity is moderately high in the Succulent Karoo (Table 2), particularly for reptiles (Vernon, 1999; Mittermeier *et al.*, 2005). There are 75 mammal species reported in the Succulent Karoo, of which four are endemic or near endemic. These are De Winton's golden mole (*Cryptochloris wintoni*, vulnerable), Van Zyl's golden mole (*Cryptochloris zyli*), Namaqua dune mole rat (*Bathergus janetta*), and a bat (*Myotis seabrai*). Major concentrations of large mammals, including elephant (*Loxodonta africana*, vulnerable status), black rhinoceros (*Diceros bicornis*, critical status), mountain zebra (*Equus zebra*), quagga (*Equus quagga*), giraffe (*Giraffa camelopardalis*), and African buffalo (*Syncerus caffer*), once roamed the plains and gallery forests along the Orange River in the Succulent Karoo. These populations have now disappeared. Small herds of gemsbok (*Oryx gazella*) and springbok (*Antidorcas marsupialis*) are present today.

The avifauna of the Succulent Karoo includes approximately 226 species, one of which is endemic, Barlow's lark

Table 2 Biodiversity and endemism of vascular plants and vertebrates in the Succulent Karoo

Taxonomic group	Species	Endemic species	Percent endemism
Plants	6356	2439	38.4
Mammals	75	2	2.7
Birds	226	1	0.4
Reptiles	94	15	16.0
Amphibians	21	1	4.8
Freshwater Fishes	28	0	0.0

Mexico City: CEMEX.

(*Certhilauda barlowi*). Other species in the biome include the black harrier (*Circus maurus*, vulnerable status) which has the most restricted range of the world's 13 harrier species, Karoo bustard (*Eupodotis vigorsii*), Ludwig's bustard (*Neotis ludwigii*), Karoo chat (*Cercomela schlegelii*), dune lark (*Certhilauda erythrochlamys*), and dusky sunbird (*Nectarinia fusca*).

Reptile diversity is relatively high in the Succulent Karoo, with approximately 94 species, of which 15 are endemic. All of the endemics are geckos and lizards, representing about a quarter of the nearly 60 geckos and lizard species in the biome. These endemics include seven species of girdled lizards of the genus *Cordylus*, including the armadillo girdled lizard (*C. cataphractus*, vulnerable status). This lizard has a heavily armored body and spiny tail, and is known for rolling into a tight ball when threatened. As in the other parts of South Africa, tortoise diversity is high in the Succulent Karoo with seven taxa, two of which are endemic. These are the Namaqualand tent tortoise (*Psammobates tentorius trimeni*) and the Namaqualand speckled padloper (*Homopus signatus signatus*).

Amphibians are poorly represented in the Succulent Karoo with 21 species. All of these species are frogs, and only one is endemic. This is the desert rain frog (*Breviceps macrops*, vulnerable status), which occurs along the Namaqualand coast of South Africa north to Luderitz in southwestern Namibia.

There are approximately 26 species of freshwater fish in the Succulent Karoo, none of which are endemic.

Invertebrates

Invertebrate diversity is relatively high in the Succulent Karoo, and evidence suggests that more than half of the species in many insect groups are endemic (Vernon, 1999). Of the 50 species of scorpions found in the hotspot, nearly 22 are endemic. Monkey beetles, which are almost exclusively found in southern Africa, are concentrated in the area. Along with many types of wasps and bees, these beetles pollinate a diverse assemblage of endemic plant species (Colville *et al.*, 2002). Perhaps the most unusual invertebrates found here are the long-tongued flies (Nemestrinidae), which can have mouthparts up to 50 mm long. The flies are the exclusive pollinators of 28 different plant species in Namaqualand (Manning and Goldblatt, 1996).

Plant Growth Forms and Vegetation Structure

The growth form mix of Namaqualand communities is unique among the world's desert ecosystems. Dwarf (<0.5 m) succulent shrubs (chamaephytes), mainly members of the Mesembryanthemaceae, Crassulaceae, and Asteraceae, are the dominant growth form over much of the Succulent Karoo, particularly in Namaqualand (Cowling *et al.*, 1994, 1999). Such a dominance of leaf succulents contrasts sharply with other deserts, including winter-rainfall ones, where this growth form is rare (Esler *et al.*, 1999). Many but not all of these succulents utilize Crassulacean acid metabolism (CAM) metabolism, with both obligate CAM and CAM flexibility present (Rundel *et al.*, 1999).

Many Succulent Karoo leaf succulents have shallow (0.1–0.2 m) rooting systems (Eccles *et al.*, 1999; Esler *et al.*, 1999; Carrick, 2003), even when growing in deep soils. A consequence of this unusual below- and aboveground morphology is that members of this growth form are vulnerable to drought-induced mortality after rare episodes of lower-than-average rainfall. Indeed, in contrast to many other desert ecosystems where the dominant perennial component is very long-lived, many of Namaqualand's leaf succulents have relatively short lifespans (5–10 years) (Jürgens, 1991).

A unique feature of the succulent flora of the Succulent Karoo is the presence of numerous minute (<25 mm tall) succulents belonging to the Mesembryanthemaceae (e.g., *Argyroderma*, *Conophytum*, and *Fenestraria*), Crassulaceae (*Crassula* and *Tylecodon*), Portulacaceae (*Anacampseros*), and Asphodelaceae (*Bulbine*, *Haworthia*) (van Jaarsveld, 1987). Many of these grow embedded in the soil with only their upper surface exposed. The occurrence of such minute perennial growth forms is paradoxical in the context of a desert environment since their small storage organs offer little capacity to endure prolonged moisture stress. Many species grow in shaded rock crevices where they are sheltered from excessive radiation and can exploit run off from rainfall, fog, and dew, whereas others are associated with exposed sites, especially quartz fields (Schmiedel and Jürgens, 1999). Ultimately, the evolution of this intriguing growth form would only be possible in an environment characterized by low but highly predictable inputs of moisture, thereby enabling plants to replenish moisture reserves on a regular basis. Indeed, there is good evidence that in southern Africa, succulence, especially the incidence of dwarf leaf succulent forms, is correlated with rainfall reliability and seasonality (winter rain) rather than annual totals (Cowling *et al.*, 1999).

Taller succulent shrubs and succulent trees are relatively uncommon in the flora of the Succulent Karoo. Many of the larger shrubs are stem succulent *Euphorbia* species, which are particularly common in the warmer and drier northern reaches, especially the greater Richtersveld. This area is also home to most of the biome's small but charismatic arborescent succulent flora, namely *Aloe dichotoma*, *A. pillansii*, *A. ramosissima* (Asphodelaceae), and *P. namaquanum* (Apocynaceae). Shrubs with drought-deciduous, orthophyllous leaves, and aphyllous forms, which comprise the dominant perennial cover in other warm, winter-rainfall deserts (Esler *et al.*, 1999), are relatively rare in the Succulent Karoo where the great majority of nonsucculent woody species are evergreen (Cowling *et al.*, 1994). Evergreen shrubs and trees include lineages endemic to the Karoo-Namib Biome (e.g., *Pteronia* and other Asteraceae) as well as species of tropical affinity, related to southern Africa's extensive subtropical thicket ecosystems. The latter, a relatively small flora comprising species of *Euclea*, *Diospyros* (Ebenaceae), *Rhus*, *Ozoroa* (Anacardiaceae), *Ficus* (Moraceae), and *Schotia* (Fabaceae), are mainly restricted to water courses and run-on sites such as the base of large, granite domes. These tall shrubs and low trees are likely relicts of the late Tertiary, summer-rainfall scrub forests or thickets that once dominated local landscapes of the Succulent Karoo. They are extremely long-lived, have vertebrate-dispersed propagules, and probably establish seedlings

on rare occasions. This life history contrasts strongly with that exhibited by the short-lived and recruitment-dependent lifestyles of most other Namaqualand perennials (Cowling *et al.*, 1999).

Another unique feature of the Succulent Karoo growth form mix is the high diversity and local abundance of geophytes. Namaqualand is home to approximately 480 species (17.5% of the flora) comprising approximately 100 genera in 19 families. At a smaller spatial scale, petaloid monocot geophytes make up approximately 16% of the flora (550 spp. in 150 km²) at Goegap Nature Reserve in the Namaqua Rocky Hills (van Rooyen *et al.*, 1990), and nearly one third of the flora (280 spp. in 1.2 km²) at Nieuwoudtville on the western fringe of the Hantam-Roggeveld bioregion. The proportional representation of geophytes in other semiarid, winter-rainfall biomes is much lower. Namaqualand geophytes encompass a wide variety of leaf types, including species with large, broad leaves fully pressed against the soil surface as well as species with tightly coiled and variously pleated leaves. Storage organ size varies from very large in many amaryllids to very small in *Oxalis*. However, the majority of species have small storage capacity; bulbs and corms of most geophytes are 1–3 cm in diameter. If geophytes are functionally interpreted as underground succulents, then their success in Namaqualand, like that of small-bodied aboveground succulents, may partly result from the biome's reliable moisture regime (Procheş *et al.*, 2005).

Annuals, which are not especially conspicuous in undisturbed vegetation, are nevertheless an important component of the Namaqualand flora, comprising 28% of the flora at Goegap Nature Reserve (van Rooyen *et al.*, 1990). Generally, proportional representation of annuals is much lower than in semiarid, winter-rainfall regions of the Mediterranean Basin and the New World. Spectacular displays of spring-flowering annuals, especially on old fields, are a popular tourist feature. The reliability of this display, which is marketed as an annual ecotourism event, is a function of the biome's predictable rainfall regime (Cowling and Pierce, 1999).

Threats to the Succulent Karoo

Two major threats to the ecology and biodiversity of the Succulent Karoo have been identified. These are threats from global climate change and threats from land degradation. The potential impacts of global change are large. Biome-level approaches likely underestimate the risk of species diversity loss from climate change impacts in the Succulent Karoo biome because of the large number of narrow range endemics that would likely suffer significant range dislocation with changing conditions (see Midgley *et al.*, 2002).

Irreversible land transformation associated with cultivation and urban areas in the Succulent Karoo is not extensive because of the low population density of the area. Extensive livestock dominates 90% of the biome, and it is this land use that has the greatest impact on biodiversity. For example, in the Little Karoo, 28% of the area of Succulent Karoo vegetation has been irreversibly transformed by overgrazing (Thompson *et al.*, 2009). Although overgrazing in communal lands

represents a threat to the biota of the Succulent Karoo, the recent purchase of 330,000 ha by the South African government for communal landowners should go some way to alleviating population pressures that were a consequence of past apartheid policies. However, stocking rates on newly acquired lands will need to be conservative to maintain conservation values (Hoffman *et al.*, 2007; O'Farrell *et al.*, 2010).

Diverse groups of grazing animals were once widely present in the Succulent Karoo, with seasonal migrations from lowlands (winter) to uplands (summer). As a result of the demise of these herds, grazing as a land use is not incompatible with biodiversity conservation if managed properly. Well-managed grazing may help maintain available niches for plant diversity. There are sufficiently extensive areas of intact habitat for many options to design and implement large conservation corridors (Cowling *et al.*, 1999; Desmet *et al.*, 2002). Implementation will, however, require some restoration in mined and severely overgrazed areas and mechanisms to reduce grazing pressure.

Nevertheless, the Succulent Karoo is vulnerable to land use pressures from overgrazing on communal lands, ostrich farming in the southeast, mining activities, and the illegal collection of plants and animals for trade. Of these, the greatest threats to biodiversity are associated with overgrazing (Alsopp, 1999; Todd and Hoffman, 1999) and mining. Overgrazing is most problematic in communal areas, which support at least double the prescribed stocking rate. Agriculture is restricted to a limited number of irrigable habitats that collectively occupy a small area. Similarly, off-road impacts are also restricted spatially. In the Southern Karoo ostrich farming has seriously transformed large areas. Diamond mining along the northwestern coast of South Africa and southwestern coast of Namibia has had major impacts on local areas but protected other pristine areas (Desmet and Cowling, 1999a).

Succulent Karoo habitats and species are inadequately represented in protected areas; only 3.5% of the biome is formally protected in seven statutory reserves (Driver *et al.*, 2003), the largest of which is the 162,445 ha Richtersveld National Park, where livestock grazing is permitted. Owing to the high turnover of species along environmental and geographic gradients, almost the entire Succulent Karoo will be required to achieve representation targets for its entire species (Lombard *et al.*, 1999). Therefore, the current conservation strategy – supported by numerous local and international conservation organizations that participate in the Succulent Karoo Ecosystem Planning (SKEP) project – is to identify and implement incentives to encourage good stewardship on private and communal land, and to purchase land for protected areas in priority sites that can sustain tourism ventures. Good progress is being made on both fronts. For example, 3.2 million ha will shortly be included in protected areas associated with the Sperrgebiet–Ai–Ais–Richtersveld Transfrontier Park; approximately 50,000 ha have been recently added to the protected area system in the Kamiesberg, Sandveld, and Vanrhynsdorp bioregions; and approximately 20,000 ha to those in the Little Karoo. SKEP has initiated numerous community-based and private conservation initiatives, all of which bode well for the long-term conservation of the Succulent Karoo.

Glossary

Allelochemical A bioactive secondary metabolite with no known major function in primary metabolism but with the capacity to affect the growth, survival, or behavior of target organisms. Many allelochemicals act as chemical defense agents, although they may also mediate beneficial interactions with the targets.

Bootstrap support A method of attempting to estimate confidence levels of inferred relationships in phylogenetic trees. The bootstrap analysis resamples the original data matrix with replacement of the characters and reconstructs the tree. The bootstrap support for any internal branch is the number of times it was recovered during the bootstrapping procedure.

Clade A group of species that shared a common ancestor (i.e., monophyletic).

Heterokonts A monophyletic group (also known as *stramenopiles*) that includes all cells with heterodynamic flagella: the mature flagellum bearing small tripartite tubular hairs termed *mastigonemes* and the second being smooth.

Maximum likelihood (ML) A method of inferring phylogenetic relationships using a prespecified (often user-specified) model of sequence evolution. Given a tree (a particular topology, with branch lengths), the ML process

asks the question, "What is the likelihood that this tree would have given rise to the observed data matrix, given the prespecified model of sequence evolution?"

Microsatellite Short tandem repeats (e.g., AC_n, where *n* > 8) of nucleotide sequences; the tandem units can be dinucleotides, trinucleotides or tetranucleotides. Each individual should have a unique number of repeat units for each microsatellite. When two individuals share the same number of repeat units, then they are more closely related than those whose repeat units differ in number.

Molecular clock A hypothesis that mutation rates and substitution rates do not vary among lineages in a tree, thus the timing of divergences can be dated from known times of divergence in the fossil record. However, it has been shown that rates of evolution along a lineage can vary. Two different kinds of clocks can be used: a fixed or a relaxed clock, depending on whether the rate of evolution is allowed to vary.

Outgroup A species or other taxonomic group chosen to establish the root of any phylogeny

Ribotyping Fingerprinting of genomic DNA restriction fragments that contain all or part of the ribosomal RNA gene to identify and distinguish among strains or species, which are thereby defined as *ribotypes*.

Distribution and Biogeography

Harmful marine algal taxa are globally distributed from tropical to polar latitudes and occupy ecological niches ranging from brackish water, such as the Baltic Sea, to oceanic environments. Nevertheless, high-biomass harmful blooms tend to be predominant in coastal and shelf seas and high-magnitude effects are most often expressed in these areas. Whereas an apparent global increase in the frequency, magnitude, and biogeographical range in harmful algal blooms (HABs) over the last several decades has often been cited and appears to be legitimate in a general sense (Hallegraeff, 1993) (Figure 1), the effects on local and regional biodiversity remain unresolved. Mechanisms invoked for the "global spreading hypothesis" (Smayda, 1990) include transport of exogenous species via ship ballast-water transport or transfer of aquaculture stock, changes in ocean currents, and human intervention in coastal zones (e.g., increased eutrophication, coastal engineering, dredging, and sediment disruption). The socioeconomic impact of HABs has clearly increased in recent years, perhaps partly caused by accelerated and modified use of coastal resources, but it is premature to conclude that this accurately represents verifiable changes in biodiversity. Enhanced scientific awareness and

refined monitoring programs for HAB taxa and associated toxins have also contributed to the apparent global increase scenario.

Whether or not discovery of previously undetected or undescribed HAB taxa in a new environment represents a true shift in biodiversity or merely reflects inadequate observations of cryptic species is often difficult to determine. There are, however, well-documented cases of apparent range extension of HAB species and associated syndromes, often rather suddenly, into new environments. For example, until recently, the dinoflagellate *Karenia brevis* responsible for neurotoxic shellfish poisoning (NSP) was apparently confined to the Gulf of Mexico and the east coast of Florida. However, in 1987, an unusual northward flow pattern of the Gulf Stream apparently distributed a major bloom of *K. brevis* into North Carolina waters, and since then such blooms are recurrent along the coast of the Carolinas (Tester *et al.*, 1991). Extreme weather events, such as hurricanes, are known to expand the existing distribution of cyst-producing toxic dinoflagellates. As a classic example, a toxigenic population of the dinoflagellate *Alexandrium tamarense* was apparently introduced from coastal Nova Scotia to New England, where it established resident populations as far south as Cape Cod in the aftermath of a hurricane in 1972 (Anderson, 1994).

(a)

(b)

Figure 1 Distribution of events up to (a) 1970 and (b) 2009, respectively, where paralytic shellfish poisoning toxins were detected in shellfish or fish, thereby providing strong circumstantial evidence for a range expansion in the distribution of the causative toxigenic dinoflagellate blooms. Reproduced with permission from US National Office for Harmful Algal Blooms.

Phylogenetic and Taxonomic Relationships

The HAB phenomenon is characterized based on a societal definition (“harmfulness”) and thus not surprisingly the associated taxa do not fall neatly into tight taxonomic or monophyletic groups. Marine HAB events have been attributed to members of various eukaryotic algal groups, including dinoflagellates (Dinophyta), prymnesiophytes or haptophytes (Haptophyta), diatoms (Bacillariophyta), raphidophytes (Raphidophyta), and pelagophytes (Pelagophyta); certain cyanobacteria from marine and brackish habitats are also included because of their consequences to ecosystems and human health. In the following sections, the authors discuss three major marine groups of harmful algae.

Dinoflagellates

Origin of the Group

The dinoflagellates are monophyletic, with *Oxyrrhis* (pre-dinoflagellate) lying outside the core dinoflagellates, and sister to the perkinsid flagellates that cause malaria (Apicomplexa) with high bootstrap support to form a clade that is sister to the ciliates (e.g., *Paramecium*), again with high bootstrap support (Leander and Keeling, 2004). Collectively, these groups comprise the superphylum or kingdom Alveolata (Adl et al., 2005), defined morphologically by the series of cortical membranes or membrane bags beneath the plasmalemma and tubular cristae in the mitochondria. A less robust sister relationship (<50%) is recovered in most phylogenetic trees with the stramenopiles or heterokont organisms (Leander and Keeling, 2004), which together with the cryptomonads and haptophytes form the chromalveolates.

The evolution and morphological adaptation of the dinoflagellates, leading to a final radiation of the free-living autotrophic forms, has been reviewed (Saunders et al., 1997). In this scheme, the Noctilucales, which undergo an unusual gametic meiosis and lack chloroplasts, are basal to the core dinoflagellates. Myzotosis or peduncle feeding, whereby a tube from a heterotrophic dinoflagellate attaches to a prey cell and the content of the prey cell is sucked into the predator, is proposed to have evolved early in the dinoflagellates. Many dinoflagellates possess a membrane-bound cell wall, known as a *theca*, that is divided into plates of cellulose (*armor*) within membrane vesicles. The tabulation of these plates (number, structure, and orientation) provides a distinctive morphological feature for taxonomic and phylogenetic analysis. Subsequent to the radiation of the core dinoflagellates, there are three alternative evolutionary hypotheses to explain the separation of thecate and nonthecate genera (Bujak and Williams, 1981), viz., the plate increase, the plate reduction, and the plate fragmentation models, with the first and third models placing the naked or nonthecate Gymnodiniales in a derived position. The peridinioid (thecate) taxa are in a different evolutionary position in each of the three models.

New phylogenetic trees derived from molecular data must be evaluated in light of these evolutionary schemes based on morphology, but there are few such trees covering the entire range of dinoflagellates, with most molecular trees focusing

only on a group of species or closely related genera. Saldariaga et al. (2004) have produced one of the earliest trees that sampled across most major core dinoflagellates. Using ciliates as an outgroup, the parasitic and atypical taxa diverge in exactly the sequence predicted by their morphological features until the divergence of the core dinoflagellates. After these divergences, clades of nonthecate gymnodinioid dinoflagellates diverge several times, alternating with clades of thecate peridinioid dinoflagellates. Each clade consists of monophyletic well-supported genera, with the exception of *Gymnodinium*, which is paraphyletic. However, relationships between the clades are not supported. There is a final divergence of the Gonyaulacales, but the Prorocentrales are paraphyletic; thus no real support is provided for any of the morphological models. Adding more taxa to the tree has not really improved the situation but has yielded a few new surprises. Figure 2 shows a tree of dinoflagellate phylogeny from a maximum likelihood analysis of the 18S rRNA gene. Divergences from the ciliates to the core dinoflagellates follow a similar pattern as seen in the other trees. The core dinoflagellates diverge simultaneously into four major clades. The first major clade contains a mixture of gymnodinioid and peridinioid taxa with nonthecate *Amphidinium* spp. often occurring as a basal divergence in a peridinioid clade, which suggests that a naked form gave rise many times to a thecate genus. Dinophysiales are a basal divergence, and the Prorocentrales are split into benthic and planktonic clades not too distantly related. Hoppenrath and Leander (2010) used the heat shock protein (HSP) 90 gene and Zhang et al. (2007) used three genes to find that the Prorocentrales were a monophyletic lineage. The second major group in the large rRNA tree (Figure 2) is a smaller gymnodinioid clade. The third major clade contains a mixture of gymnodinioid and peridinioid taxa. However, Noctilucales are embedded in this clade, a position also recovered in the HSP gene tree by Hoppenrath and Leander (2010). Gonyaulacales are a final divergence. The fourth major clade consists primarily of naked dinoflagellates with the Suessiales (found as coral endosymbionts) as a final divergence. With a three-gene concatenated dataset, Zhang et al. (2007) found *Amphidinium* at the base of the core dinoflagellate lineage. Their major well-supported divergence was between endosymbiotic taxa and free-living taxa, with the Gonyaulacales being monophyletic with one exception.

Origin of the Toxic Species

The toxigenic species are not a monophyletic group and although the various genera containing toxic members are more or less monophyletic, they are distributed among the four different major clades shown in Figure 2. The dinoflagellate toxins are structurally diverse, ranging from linear and macrocyclic polyketides to tetrahydropurine alkaloids, and are derived via divergent pathways. Thus, the various major types of toxins likely evolved more than once among the dinoflagellates, and perhaps even within clades. Alternatively, if toxins have evolved only once, then there have been many multiple losses of toxigenic capability. Clade 1 includes the genera *Dinophysis* and *Prorocentrum* associated with diarrhetic shellfish poisoning, the karlotoxin-producing genus *Karlodinium* sister to *Azadindium*, which contains an azaspiracid toxin-producing

Figure 2 RaxML phylogenetic tree from 1490 small subunit rRNA sequences from dinoflagellates and closest sister groups. The core dinoflagellates have a simultaneous divergence of four major clades. All major clades are collapsed, showing the dominant cell morphology in the clade (either peridinioid (thecate) or gymnodinioid (naked)). Toxic genera are mentioned where they occur throughout the tree.

species and the ichthyotoxic *Pfiesteria*; each of these genera is in a different monophyletic clade within clade 1 and have nontoxic species as their closest sister group. The NSP toxin producers of the genus *Karenia* are found in clade 2. In clade 3, the monophyletic genus *Alexandrium*, containing approximately a dozen species that produce paralytic

shellfish poisoning (PSP) toxins, is sister to the ciguatera toxin-producing genus *Gambierdiscus*, which in turn is sister to the thecate genus *Pyrodinium*, including *P. bahamense* var. *compressum* that also synthesizes PSP toxins. *Gymnodinium catenatum*, a nonthecate PSP toxin producer, is the only toxic species found in clade 4.

Haptophytes

Origin of the Group

Haptophytes are unicellular algae that are important members of the marine phytoplankton involved in many important biochemical cycles. Cells possess two smooth flagella and another organelle, called a *haptonema*, inserted between the flagella. The cells are covered by organic scales, which are calcified in one group, the coccolithophorids. The true sister group of the haptophytes is unknown but is weakly allied with the Cryptophyta (see review in Lane and Durnford, 2010). Haptophytes comprise two clades that correspond to the two classes. In the class Coccolithophyceae are several clades that correspond to order level taxonomy in the group.

Origin of the Toxic Species

Among the haptophytes, only a few planktonic species are responsible for harmful and nuisance events through the

production of high biomass, which may be accompanied by apparent toxicity effects on marine fauna – for example, mass fish mortalities. Members of the genera *Chrysochromulina* and *Prymnesium* are associated with ichthyotoxicity in coastal marine, brackish, and even freshwater systems, whereas *Phaeocystis* blooms can produce copious foam that forms unpleasant aggregations on beaches but are not known to be toxigenic. In Figure 3, only the order Prymnesiales is shown because all toxic haptophyte species fall into one clade, namely, the family Prymnesiaceae within this order. This is in contrast to the dinoflagellates for which toxigenic taxa are distributed throughout the phylogenetic tree.

The genus *Chrysochromulina* is paraphyletic and falls into two clades, one of which contains the toxic species as a separate and well-supported subclade. The high bootstrap and morphological support for major clades and subclades in the Prymnesiales justified the recent substantial taxonomic revision (Edvardsen *et al.*, 2011), whereby all species in one of

Figure 3 Consensus Bayesian tree based on concatenated nuclear 18S and partial 28S and plastid 16S ribosomal encoding DNA sequences of members of the Prymnesiales. *Cruciplacolithus neohelis*, *Emiliana huxleyi*, and *Pleurochrysis carterae* were used as outgroups. Redrawn from Edvardsen B, Eikrem W, Throndsen J, Saez A, Probert I, and Medlin LK (2011) Ribosomal DNA phylogenies and a morphological revision set the basis for a new taxonomy of the Prymnesiales (Haptophyta). *European Journal of Phycology* 46: 202–228.

the subclades have been transferred into *Prymnesium*. This genus includes the toxic species *Chrysochromulina polylepis* (now as *Prymnesium polylepis*); with *Prymnesium parvum*, these are the two main fish-killing species in the haptophytes.

Heterokonts

Origin of the Group

The Heterokonts are another major eukaryotic radiation, often linked to the alveolate lineage with moderate bootstrap support (Leander and Keeling, 2004). The basal lineages are heterotrophic and photosynthetic lineages are the last major divergence in the group (Cavalier-Smith and Chao, 2006). All toxigenic and otherwise harmful groups of heterokont algae occur within the photosynthetic lineage.

Origin of the Toxic Species

Within the pigmented heterokonts, two major classes or phyla include many toxic species. Among the class Raphidophyceae, some strains of the genera *Chattonella* and *Heterosigma* at high cell concentrations can kill fish, but the exact mode of action and the nature of the “toxins” remains unresolved (Rensel and Whyte, 2003). Other raphidophytes, such as members of the freshwater genus *Gonyostomum*, may secrete copious amounts of mucilage that are detrimental to fish gills but show no evidence for a defined toxin.

Among the Bacillariophyta, harmful effects may be produced by alternative mechanisms, primarily by toxin production or by physical-mechanical damage. In the latter case, some centric diatoms, such as *Chaetoceros* spp., have a life form (cells in a chain with long spiny protuberances called *setae*) that can clog fish gills and thereby kill fish, but they do not produce any toxins. Toxin producers are only found so far among the marine pennate diatoms (Figure 4), largely or exclusively belonging to the genus *Pseudo-nitzschia*. This genus contains more than a dozen species known to produce the neurotoxin domoic acid, the causative agent of amnesiac shellfish poisoning. Most of the older-named species were originally placed in the genus *Nitzschia* because the genus *Pseudo-nitzschia* was originally its own genus before it was reduced to a section of the genus *Nitzschia* and then elevated back to genus status by Hasle (1993). From a diversity perspective, the toxigenic and taxonomic status remains confusing because extensive molecular analyses continue to recover cryptic species. As a result, many toxin-producing *Pseudo-nitzschia* have been transferred or promoted from *forma* or varieties of *Pseudo-nitzschia* to species level, and new species have been described, based on morphological characteristics normally at the limit of resolution of the light microscope. Electron microscopy must be used to confirm their identity in field samples as well as to describe them as new taxa. Thus, name changes among the taxa abound. For example, the first pennate diatom known to produce domoic acid was originally reported as *Navia pungens* *forma multiseries*, then as *Pseudo-nitzschia pungens* f. *multiseries*, and finally as *P. multiseries* (Bates et al., 1998). Early reports of domoic acid in marine species of *Nitzschia sensu stricto* and the brackish water species, *Amphora coffaeiformis*, require confirmation. Further complications arise from the fact that toxigenicity may be lost in cultures without

sexual production and domoic acid production within strains is highly inducible or repressible. Finally, even among clearly defined strains belonging to the same morphospecies or genetic species of *Pseudo-nitzschia*, the capacity for domoic acid production may be highly inconsistent and is often related to the stage in the growth cycle with many strains only becoming toxic as they enter stationary growth.

Population Genetics and Bloom Dynamics

Protein variants known as *isozymes*, with the same enzymatic functional role but differing slightly in 1°, 2°, 3° or 4° structure, were the first molecular markers for species- and population-level studies on marine species, including those of HAB taxa. Small differences in their molecular size or isoelectric point enable separation of isozymes by electrophoresis. Isozymes were the markers of choice for early investigations because they were quick and easy to resolve and detect, and they reflect primary gene products. But the requirement that isozymes must still be functional in the biochemical pathways strongly limits the number of possible mutations and, therefore, the number of alleles and the heterozygosity of this marker. Another disadvantage of this marker is that protein content and enzyme activity and thus the detection of isozymes is strongly influenced by the environment and physiological status of the cells.

The goal of most early molecular studies on microalgae based on isozyme analysis was to resolve species-level issues among species with conflicting or little morphological resolution rather than to study genetic structure within bloom populations. Thus, the early isozyme results were applied to the recognition of cryptic species or the recognition of previously discounted morphological markers for separation of members of a species complex. In the first inter- and intra-specific study of members of the *A. tamarense* and *catenella* species complex, isozyme analyses showed a high degree of enzymatic heterogeneity among isolates from the west coasts of the USA and Canada but indicated that isolates from the same locality were most closely related (Cembella and Taylor, 1986). In contrast, a relative lack of enzymatic heterogeneity was revealed by a similar analysis of *Alexandrium* populations from the east coast of the USA (Hayhome et al., 1989). Isozyme data suggested a common origin for the East Coast populations and supported the dispersal hypothesis along the East Coast of the USA from Canada down to Massachusetts, as related to hydrographic events dissipating a massive red tide that occurred in 1972. Isolates of the dinoflagellate *Gambierdiscus toxicus* from similar geographical regions within the tropics were shown not to be closely related by isozyme comparison, which suggested a multiclonal origin for these populations (Chinain et al., 1997). Among HAB taxa, isozyme studies are largely confined to the dinoflagellates, as there are no published studies for the toxic haptophytes and only very preliminary investigations have been conducted on toxic *Pseudo-nitzschia* spp. (Skov et al., 1997).

As a consequence of the limitations of isozyme analysis to reflect genomic differences at high resolution, alternative marker types were later developed that directly addressed the nucleic acid level and hence are relatively refractory to

Figure 4 Bayesian analysis of 920 diatom taxa rooted with the Bolidomonads. Three monophyletic classes occur, each shown in a different color. The toxic diatom genus *Pseudo-nitzschia* occurs as one of the most derived or advanced pennate diatom genera. Redrawn from Bowler C, Allen AE, Badger JH, *et al.* (2008) The *Phaeodactylum* genome reveals the dynamic nature and multilineage evolutionary history of diatom genomes. *Nature* 456: 239–244.

environmental variation and shifts in physiological status. Diversity below the species level is now most robustly measured by DNA- or RNA-fingerprinting methods of which microsatellites are the most computationally intensive. Recently, there has been a rapid increase in studies using DNA microsatellite markers to estimate gene flow and resolve dispersal mechanisms in natural populations as evidenced by the development of microsatellite markers for many species, with particular focus on harmful species (see references in Table 1). The primary limiting factor to developing microsatellites and performing ecological analyses on large spatial and temporal scales is the need to make single-cell isolations from planktonic populations and to maintain them in culture for analysis. Amplification of microsatellites from single

dinoflagellate cells (Henrichs *et al.*, 2008) represents a way to overcome culture and sampling bias for planktonic organisms.

Cryptic speciation in several harmful algal species has been studied in more detail using sequence analysis of rapidly evolving genomic regions, such as the internal transcribed spacer (ITS) and the hypervariable D1/D2 region of the large subunit (LSU) rRNA gene. Within the *Alexandrium tamarense-fundyense-catenella* species complex, perhaps the most intensively studied HAB group, isolates were shown to be related by geographic origin rather than by morphological affinities (Scholin *et al.*, 1995), with the rRNA gene data essentially confirming the early isozyme analyses. *Alexandrium* isolates from within the species complex will interbreed more successfully if they have similar isozyme patterns from two

Table 1 Summary of microsatellite studies on harmful dinoflagellates

Species	Source
<i>Alexandrium tamarense/fundyense/catenella</i> NA	Nagai, <i>et al.</i> (2004, 2007a), Alpermann, <i>et al.</i> (2009)
<i>Alexandrium tamarense/fundyense/catenella</i> TA	Nagai, <i>et al.</i> (2006b), Nishitani, <i>et al.</i> (2007)
<i>Alexandrium minutum</i>	Nagai, <i>et al.</i> (2006a)
<i>Cochlodinium polykrikoides</i>	Nagai, <i>et al.</i> (2009)
<i>Heterocapsa circularisquama</i>	Nagai, <i>et al.</i> (2007b)

<i>Karenia brevis</i>	Renshaw, <i>et al.</i> (2006)
<i>Lingulodinium polyedrum</i>	Frommlet and Iglesias-Rodríguez (2008)
<i>Akashiwo sanguinea</i>	Cho, <i>et al.</i> (2009)

All species listed are known to produce an identifiable toxin, except as indicated in bold.

different locations than will isolates from the same locations but with different isozyme patterns (Sako *et al.*, 1990). Currently, the geographic clade names have been replaced with numbers because their present-day known distribution exceeds the original areas (Lilly *et al.*, 2007). Thus, the North American clade is now termed Group I with primarily a Pacific distribution but also found in northern Europe, the Mediterranean clade of Group II is still endemic to the Mediterranean; the Western European clade equals Group III with one Japanese relative, the temperate Asian clade equals Group IV with relict populations in the Mediterranean, and the tropical Asian clade equals Group V known only from Australia.

The worldwide biogeographic dispersal of ancestral populations of the *A. tamarense* species complex from the Pacific into the Atlantic has also been hypothesized from rRNA gene data. Using a molecular clock, John *et al.* (2003) proposed a scenario for the biogeographic history of this complex from a single global ancestor. The later divergences of the nontoxic Western European clade from the toxic temperate Asian (TA) could be dated to the closing of the Tethys Sea, which likely explains the presence of relict cells of this clade in the Mediterranean. The separation of the nontoxic Mediterranean clade from the toxic North American clade was dated to the rising of the Isthmus of Panama. With time, the Mediterranean clade went extinct in the western tropical Atlantic waters, but it thrives today in the Mediterranean, where it is now endemic.

Microsatellites have clarified the origin of the TA clade of the *Alexandrium tamarense–fundyense–catenella* species complex. Lilly *et al.* (2002), comparing Mediterranean and Asian strains with LSU rRNA sequence data, concluded that the presence of TA strains in the Mediterranean was a clear case of ballast-water introduction. Penna *et al.* (2005), using ITS sequence data, also concluded that it was likely the result of ballast-water introduction. Masseret *et al.* (2009), using microsatellites, showed the Mediterranean populations to be clearly distinct and distant from the Asian strains but could not offer any reasonable explanation for their occurrence in the Mediterranean. However, referring back to the historical biogeography of the species complex by John *et al.* (2003), the closing of the Tethys Sea, which is the vicariant event separating the West European from the TA strains, the presence of the TA genotypes in the Mediterranean is likely a relict population from when the two groups were once joined. Their notable presence in Mediterranean French lagoons is likely caused by a change in environmental conditions that yield

dramatic blooms. The first hierarchical study of genetic diversity has been conducted on populations of *A. tamarense* (NA clade) off the Orkney Islands, UK (Alpermann *et al.*, 2009, 2010). On a global scale, the Scottish east coast populations found near the Orkney Islands are more closely related to Japanese Pacific isolates than to populations on the east coast of North America, which suggests that the Orkney populations were introduced to that region by cells transported directly across the Arctic Ocean. This interpretation is in contrast to the hypothesis put forward by Medlin *et al.* (1998) that these populations entered from the Pacific and moved along coastal pathways of the eastern side of North America until they reached the Gulf Stream, which carried them across to the Scottish east coast. Moving to the diversity of local populations, at one site off the Orkney Islands, four populations were discovered that could interbreed, and these populations were proposed to represent different year classes that had hatched from local cyst beds (Alpermann *et al.*, 2010).

Karenia brevis has been shown to be a single population in the Gulf of Mexico (Renshaw *et al.*, 2006 and unpubl.) based on microsatellite analysis, although molecular probes have also supported the recognition that the Florida red tides previously assumed to be monospecific *K. brevis* blooms are often multispecific (Steidinger *et al.*, 2008). In *Alexandrium minutum*, several microsatellites have been found to occur on the same chromosome (Nagai *et al.*, 2006b). *Alexandrium minutum* from the Atlantic Ocean and the Mediterranean Sea can be segregated into four genetic populations that more or less correspond to four regional seas in the Mediterranean and the relatedness of these four populations can be explained by circulation patterns in the Mediterranean (Casabianca *et al.*, 2012).

Among HAB taxa, most microsatellites have been developed for dinoflagellates but also for a few raphidophytes, such as *Chattonella* spp. (Demura *et al.*, 2007) and *Heterosigma akashiwo* (Nagai *et al.*, 2006b). Microsatellites for the raphidophytes were found to be very heterozygous but have not yet been applied for ecological interpretations at the population level.

Almost all dinoflagellates are nominally haploid in the vegetative stage, with exceptions found among the Noctilucales. A number of HAB species, particularly among the thecate dinoflagellates, produce a resistant benthic resting stage (or cyst) within their life history as an overwintering or survival strategy (Figure 5). Differentiation of haploid gametes

Figure 5 Schematic representation of the life history of *Alexandrium* species, typical of dinoflagellates for which the motile vegetative cells are haploid – that is, they have one set of chromosomes. Excystment from the benthic resting cyst (1) leads to formation of a motile planomeiocyte stage (2) that subsequently divides to form vegetative cells (3). Some vegetative cells become gametes, initiating the sexual phase whereby the gametes fuse (4) to yield a motile planozygote with double the number of chromosomes (5). The planozygote can transform into a resting cyst (hypnozygote) to complete the cycle or for some species can undergo a reduction division to yield a vegetative cell. Modified from Sellner KG, Doucette GJ, and Kirkpatrick GJ (2003) Harmful algal blooms: Causes, impacts and detection. *Journal of Industrial Microbiology and Biotechnology* 30: 383–406, with permission from Springer.

followed by fusion to form diploid planozygotes leads ultimately to nonmotile sexual resting cysts (or hypnozygotes) and thereby provides the opportunity for both genetic recombination and the maintenance of functional diversity within and among populations. The timing of excystment and survival success of hatched cysts as a contribution to the vegetative population or “bloom” is therefore a key determinant of the population genetic structure. This was demonstrated in a conceptual population model for the dinoflagellate genus *Alexandrium* (Alpermann *et al.*, 2009) based on the analysis of multiple isolates from a geographical population using microsatellites and amplified-fragment length polymorphism (AFLP). Clonal selection and shifts in genotype frequencies caused by variations in selective constraints of the environmental regimes is the most likely explanation for observed population genetic substructures revealed by these genetic markers. The interplay between genetic structure and population diversity, as modulated by mating compatibility within contemporaneous populations

and environmental factors affecting survival, is also supported by observation of two genetically distinct subpopulations of *A. fundyense* (Group I) in the northeastern USA, comprising either early bloom or late-bloom genotypes (Erdner *et al.*, 2011).

Apparent biogeographical distinctiveness among clades may arise via reproductive barriers based on limited sexual compatibility. Brosnahan *et al.* (2010) mated strains of Group I and Group III ribotype of the dinoflagellate *A. tamarense*, which yielded true sexual resting cysts, but the subsequently germinated cells did not survive. Such reproductive barriers are indicative that these ribotypes constitute different biological species and also suggests that such barriers may limit successful invasions of foreign ribotypes and range extension via lethal hybridizations. This interpretation is consistent with the mating compatibility model developed earlier for *A. tamarense* (as *Alexandrium excavatum*) by Destombe and Cembella (1990) based on crossing multiple clonal strains and monitoring the presence of fusing gametes, cyst formation, and subsequent germination success. This model postulates a complex spectrum of mating compatibility and affinities rather than two defined parental mating types, even within a geographical population.

Chemical Ecology in Species Interactions Affecting Diversity

As members of pelagic or benthic communities, HAB taxa are subject to species interactions that may alternatively promote or suppress the population growth rate and biomass yield. Population growth may be limited not only by abiotic factors (light, temperature, nutrients, advection) but also by species interactions, such as grazing, parasitism, viral and bacterial attack, and resource competition. Although it is often assumed that HAB taxa achieve high biomass and monospecific dominance via high intrinsic growth rates, this is not always the case. For example, many dinoflagellates, including most harmful taxa, are comparatively slow growing and poor nutrient competitors with respect to contemporaneous diatoms (Smayda, 1997).

In addition to the selective advantage of swimming behavior and vertical migration capabilities of marine flagellates, many HAB flagellates possess the ability to produce toxins or other allelochemicals that may affect species interactions (Cembella, 2003). Among the eukaryotic flagellates, these toxins include linear and polycyclic polyethers and tetrahydropurines, such as saxitoxin and analogues. Within the diatom genus *Pseudo-nitzschia*, some strains of a few species also produce the neurotoxic secondary amino acid known as domoic acid and its derivatives.

The widespread although not ubiquitous distribution of potent toxins and other allelochemicals among phylogenetically diverse groups of HAB taxa suggests that these secondary metabolites have a defined functional role and provide a selective advantage, perhaps related to competition, predator–prey interactions, or other forms of chemical communication (Legrand *et al.*, 2003). The high potency of these secondary metabolites against mammals and cultured cells led to the assumption that the compounds are

components of a “watery arms race” (Smetacek, 2001) against competitors and predators in marine ecosystems. This molecular target idea is further supported by evidence that the toxic profiles are typically stable and highly polymorphic within a clone but subject to high variation within and among species and populations (Cembella, 2003). The chemical defense hypothesis has been intensively investigated over the past three decades in studies with a wide variety of toxigenic taxa producing various toxin spectra, and in combinations with putative predators and competitors. Indeed, in a review of interactions between toxic phytoplankton and metazoan grazers, Turner *et al.* (1998) reported that in some cases exposure of grazers to toxigenic prey caused predator avoidance behavior, incapacitation, or mortality, as would be predicted from the chemical defense hypothesis. In other cases, the grazers appeared not to be negatively affected by the presence of toxins in the prey, but the responses were always highly species- and strain-specific. With respect to microzooplankton grazer interactions, such as dinoflagellates, ciliates, and other protists against toxic HAB taxa, the evidence does not typically support a chemical defense function for the known toxins (Ianora *et al.*, 2011).

This lack of general confirmation of expected toxicity responses should not be interpreted to imply that the toxins play no role in species interactions. In fact, recent studies provide evidence of co-evolutionary mechanisms in chemically mediated species interactions among predators and competitors that could lead to shifts in diversity and dominant genotypes in natural bloom populations. Waterborne cues of predatory copepods can induce a shift up in cell toxin content and changes in gene expression profiles in potential prey, such as *Alexandrium* spp. (Wohlrab *et al.*, 2010; Yang *et al.*, 2011). This functional genomic approach indicated that regulation of serine–threonine kinase signaling pathways has a major influence in directing the copepod cues into different intracellular cascades and networks in toxic prey dinoflagellates (Wohlrab *et al.*, 2010), and may serve as a survival mechanism for dinoflagellates with the capacity for toxin production.

In addition to the known toxins of high potency against mammals, many marine HAB flagellates can synthesize and release allelochemical substances (often poorly chemically characterized) that are capable of immobilizing or lysing cells of potential predators and competitors (Ma *et al.*, 2011). Although the mode of action is unknown or poorly characterized, these allelochemicals may act as “toxins” of high adaptive significance in an ecological sense because of their high lytic activity in natural populations.

The taxonomic and phylogenetic distribution of the known mammalian toxins and apparently unrelated allelochemicals is particularly intriguing from a diversity perspective. For example, the saxitoxin analogues associated with PSP are produced not only by certain species and strains of the related gonyaulacoid dinoflagellates *Alexandrium* spp. and *P. baha-mense* but also by the distantly related gymnodinioid dinoflagellate *G. catenatum*. The same toxin group then reappears in members of several cyanobacterial genera, primarily from fresh and brackish water; in the complete operon fully sequenced from *Alexandrium*, however, only three of the eight genes are of cyanobacterial origin (Hackett *et al.*, in press).

Clearly, most of the genes are of a eukaryotic and independent origin.

Most of the polyether and tetrahydropurine toxin derivatives produced among HAB dinoflagellates are constitutive metabolites; if present within a strain, the toxin composition is a rather stable phenotypic trait. In contrast, production of the neurotoxin domoic acid by some strains of the diatom *Pseudo-nitzschia* is highly inducible or repressible, depending on nutritional status and other extrinsic factors (Bates, 1998). Among HAB dinoflagellates, the toxin composition is typically represented by a suite of closely related derivatives and is fixed genetically within a clonal strain (Anderson *et al.*, 1990). This led to attempts to apply toxin profiling as a molecular fingerprint or phenotypic marker at both the species and population levels (Cembella, 1998 and references therein). The composition of saxitoxin analogues varies widely within and among *Alexandrium* species, but toxin profiles are generally distinguishable from those of other toxic dinoflagellate genera (*Pyrodinium* and *Gymnodinium*) and cyanobacteria. Within the *A. tamarensis* species, complex toxin profiles are generally too diverse and variable for species discrimination, but this chemotaxonomic marker has been successfully applied to differentiate among geographical populations within a species based on cultured isolates (Cembella *et al.*, 1987; Anderson *et al.*, 1994). Comparison of PSP toxin composition of field populations of *A. tamarensis* from different sampling sites in eastern Canada (Cembella and Destombe, 1996) showed that geographical populations from the Bay of Fundy and the St Lawrence estuary were more homogeneous in toxin composition than those from eastern Nova Scotia. Such population-level differences in toxin composition can be interpreted as an indication that the St. Lawrence populations are well mixed genetically and perhaps originate from the same cyst beds, whereas populations from eastern Nova Scotia are more reproductively isolated.

Even if the toxin profiles are genetically determined, the interpretation of biodiversity patterns and variation at the species and population levels based on toxin composition of HAB taxa is nevertheless subject to critical limitations. If based on one or a few cultured isolates, then the toxin phenotypic range is not determined and the profiles represent only those of survivor genotypes. Alternatively, if based on directly sampling of mixed field populations, the toxin profile will reflect the average of the multiple genotypes, reflecting their relative abundance and cellular toxin composition and concentration. Indeed, in an integrated study of clonal variation in toxin composition, allelochemical activity, and genetic markers (microsatellites and AFLP) among a high number of isolates (88 clones) of *A. tamarensis* from a geographical population on the east coast of Scotland, Alpermann *et al.* (2010) found high heterogeneity in all phenotypic and genotypic characteristics within the population. Despite hierarchical grouping according to toxin profiles, there was no clear linkage to the molecular markers AFLP and microsatellites or to the allelochemical activity measured as lytic effects. Although similar comparative data are not yet available for other toxigenic HAB taxa, there are preliminary indications from biogeographical studies of toxin polymorphisms (Gribble *et al.*, 2005) that such phenotypic heterogeneity and cryptic diversity within and among populations are common features.

Diversity and Global Change Processes

With respect to general biodiversity of plankton, climate-mediated shifts in ocean regimes are expected to lead to (1) range expansion of warm-water species toward higher latitudes and niche displacement of cold-water species; (2) temporal shifts in the frequency and abundance of particular taxa, including the timing of seasonal succession processes; and (3) alteration of food-web interactions, including grazing and prey selectivity. The extent to which these changes will affect the diversity and biogeographical distribution of HAB taxa (reviewed by Dale *et al.*, 2006; Moore *et al.*, 2008; Hallegraeff, 2010) will be a function of their respective ability to adapt to and colonize such emerging niches provided via changes in nutrient concentration and ratios, degree of stratification, and abiotic factors, such as temperature, pH and salinity regime, etc.

A few recent studies have attempted to establish causal links between exceptional or unprecedented algal blooms and climate shifts and anomalies (e.g., Belgrano *et al.*, 1999; Skjoldal and Dundas, 1991; Cloern *et al.*, 2005; Moore *et al.*, 2008), but conclusive evidence remains lacking. Although scenarios for predicted biodiversity shifts are often directly coupled to climate change and variability (e.g., temperature rise, oceanic carbon flux), these issues must be considered in a broader context to include synergistic or compensating interactions at the local and regional scale. For example, nutrient enrichment of coastal waters may interact with increasing temperatures and CO₂ levels to affect the frequency and abundance of sympatrically distributed HAB species, such as the raphidophyte *Heterosigma akashiwo* and the dinoflagellate *Prorocentrum minimum* (Fu *et al.*, 2008) but specific outcomes are difficult to predict in nature. As an unintended consequence on diversity, eutrophication abatement strategies may lead to a decrease in the frequency and magnitude of ichthyotoxic blooms of rapidly growing high-biomass producing species to be replaced by blooms of highly toxigenic species causing shellfish toxicity even at relatively low cell concentrations. This is apparently the case for the biodiversity regime shift in the Seto Inland Sea of Japan, with decreasing fish kills linked to blooms of raphidophytes over the last several decades but increasing incidences of shellfish toxicity associated with toxic dinoflagellates (Imai *et al.*, 2006). Such complex interactions may also account for the dramatic increase in ciguatera fish poisoning over the past century in the South Pacific, in particular in French Polynesia (Hallegraeff, 2003). The causative factors are unclear but may include reef damage by military and recreational development, increases in typhoon frequency and intensity, and climate-related effects on coral erosion and destruction via photo-bleaching and acidification. In any case, the primary causative organism *Gambierdiscus toxicus* has now apparently spread from the Great Barrier Reef into southeast Australian sea-grass beds in association with a strengthening of the East Australian Current (Hallegraeff, 2010). Within the Mediterranean region, *Gambierdiscus* populations are also expanding their distributional range (Aligizaki *et al.*, 2008), although this cannot be unequivocally linked to climate-mediated processes.

Conceptual models and hypothetical scenarios of the effects of global change on the diversity and biogeographical distribution of HAB species are based primarily on

extrapolations of variation observed over the last several decades (short timescale) or derived from the fossil record. Global change processes affecting HAB diversity are often interpreted within the context of climate variation and oscillations (atmospheric CO₂ levels, sea surface temperature, etc.), but direct anthropogenically mediated modification of coastal ecosystems via coastal engineering, introduction of invasive species and eutrophication are also expected to induce biodiversity shifts on a local and regional scale. Recent decadal scale observations, however, do tend to indicate shifts in abundance and distribution of plankton species, such as those documented from the Hardy Continuous Plankton Recorder (CPR) data from the North Sea and adjacent waters since the 1940s (Reid *et al.*, 2003). Most multidecadal sets are inadequate with respect to revealing frequency and abundance shifts of HAB plankton. The CPR transects were originally designed to focus primarily on zooplankton, and although they have proven useful for studying coccolithophorid distributions in recent years, many of the cryptic HAB taxa, particularly small-celled species, are not well represented or have been previously overlooked in the surveys.

Nevertheless, there are a few documented diversity changes in the range and abundance of particular HAB taxa, related either to interannual variation in oceanic regime or to catastrophic events such as hurricanes. Based on decadal scale analysis, there is circumstantial evidence of a coincidence between the magnitude of blooms of the toxigenic dinoflagellate *P. bahamense* in the southern Pacific and the quasi-periodic climate phenomenon known as El Niño Southern Oscillation (ENSO) (Azanza and Taylor, 2001). Exceptionally high-magnitude PSP episodes caused by blooms of the *A. tamarensis/catenella* along the Pacific Northwest coast of the USA were also temporally correlated with ENSO events in seven of nine cases between 1941 and 1984 (Erickson and Nishitani, 1985). A putative link between ENSO events and a massive offshore bloom of the toxigenic diatom *Pseudo-nitzschia* in summer 1998 along the coast of California was associated with higher than normal water temperatures in the eastern Pacific during the summer and fall of 1997 followed by a transition from El Niño to cooler La Niña conditions (Bargu *et al.*, 2010). Although the evidence is not conclusive in any of these cases, climate-mediated changes on oceanic regimes, such as ENSO and North Atlantic oscillation (Belgrano *et al.*, 1999), may prove to be a major factor in determining biodiversity shifts and periodicity in the appearance and abundance of HAB taxa, particularly in coastal zones.

As previously mentioned, rising sea surface temperatures associated with global warming may be expected to favor a range expansion toward higher latitudes, but this will also bring a disproportionate increase in the abundance of marine flagellates, which tend to thrive in warmer stratified water regimes. Rising sea surface temperatures have already been associated with increases in dinoflagellates in the North Atlantic, the North Sea, and the Baltic Sea, as well as to seasonal shifts in the timing of dinoflagellates in the plankton successional cycle (Dale *et al.*, 2006). Global warming may also tend to favor differentially blooms of cyanobacteria in marine and freshwater ecosystems, including those of harmful and toxigenic species (reviewed by Paerl and Huisman, 2008 and 2009). Nevertheless, these apparent shifts in group diversity and

dominance cannot yet be unequivocally linked to climate-mediated differential effects on particular HAB taxa. Dale *et al.* (2006) argue convincingly that because most HAB taxa are coastal or estuarine and broadly eurythermal, modest water temperature increases of a few degrees associated with global warming are unlikely to be the major determinant of their dominance and persistence.

Climate change is expected to lead to disruptive changes in wind velocity and seasonal shifts in ocean stratification parameters, such as upwelling and downwelling of coastal and shelf seawaters. Many HABs, particularly of dinoflagellates, are associated with postupwelling relaxation events in areas, such as the California coast and within the Benguela Current system off southwest Africa (Pitcher and Boyd, 1996). Wind-driven effects on HAB dynamics and diversity are linked not only to stratification but also to upwelling of macronutrients to surface waters (Kudela *et al.*, 2010). These combined wind effects tend to favor the development of blooms of toxigenic chain-forming dinoflagellates, such as those of *G. catenatum* off the Iberian coast (Fraga and Bakun, 1990) and the *catenella* morphotype of the *A. tamarensis* species complex along the west coast of North America (Langlois, 2001). In the case of the fish-killing raphidophyte *Chattonella marina* in Hiroshima Bay, Japan, blooms were apparently enhanced subsequent to typhoon-induced runoff of terrestrial nutrients, but such blooms are also likely associated with excystment triggers and the capacity for vertical migration as adaptive strategies (Hallegraeff, 2010).

With few exceptions, HAB events are typically confined to coastal and shelf seas, therefore a rise in sea level and decreased salinity associated with shifts in precipitation patterns and melting of polar ice sheets may increase the potential for blooms of species favored by low salinity and highly stratified water columns. Examples of such species would include the ichthyotoxic haptophytes, such as *Pr. parvum* and *Chrysochromulina* (now *Pr.*) *polylepis* and perhaps coccolithophorids in fjord systems. Ocean acidification linked to increasing atmospheric carbon dioxide has been predicted to have a deleterious effect on calcifying organisms, including coccolithophorids (Riebesell *et al.*, 2000). However, there is wide variation in strain response and also evidence that in complex assemblages as found in nature and not in a culture vessel increased CO₂ will actually increase calcification (Beaufort *et al.*, 2011). In principle, any change in climate could open new niches for other groups – for example, noncalcareous dinoflagellates – but it is difficult to predict whether or not harmful taxa would be particularly advantaged.

Among the thecate dinoflagellates, the benthic cyst stages (following sexual reproduction) of some species are subject to fossilization. The fossil morphotypes can be related to the vegetative stages of extant species, thereby yielding a potential paleo-oceanographic time series of the distributional shifts in the taxon. The toxigenic dinoflagellate *P. bahamense* provides a particularly instructive example of climate-mediated shifts. This species is presently restricted to tropical and subtropical coastal waters of the Atlantic, the Caribbean, and the Indo-West Pacific. Distribution of *P. bahamense* is strongly associated with mangrove-fringed areas (MacLean, 1977; Azanza and Taylor, 2001), therefore it would be expected that occurrence of this species may be reduced in distribution and even

disappear from areas subject to mangrove destruction. The fossil cyst record of this species (as *Polysphaeridium zoharyi*), extending to the substantially warmer Eocene period 50 million years ago, indicates a much wider range of distribution, including the Portuguese coast, than indicated in recent records. Although today absent from the nontropical Australian coast, approximately 100,000 years ago this species ranged as far south as Sydney Harbour (McMinn, 1989).

Given the diverse and polyphyletic evolutionary history of HAB species and the consequent lack of an apparent common ecophysiological adaptive strategy, it is difficult to construct general predictive scenarios of “winners and losers” in response to global change. Autecology of individual species and even intrapopulation responses to ecophysiological shifts must be more thoroughly investigated. Group-specific predictions based on known responses to increased temperature, enhanced surface stratification, intensification or weakening of nutrient upwelling, stimulation of photosynthesis by elevated CO₂, changes in land runoff and nutrient availability, and decreased ocean pH are clearly inadequate. Genetic diversity has been investigated in only a handful of species, so it is also impossible to predict whether or not these species have sufficient genetic diversity to withstand major climate shifts and not becoming globally or locally extinct. Certainly climate change will fragment populations and affect gene flow among them.

The Way Forward

The lack of a scientifically based definition of what constitutes a HAB taxon coupled with the multiplicity of strategies and mechanisms whereby the harmful effects are expressed suggest that it is unrealistic to expect a “unified field theory” to encompass all HAB dynamics and evolution in the context of biodiversity. Until recently, ecophysiological and genetic studies on HAB taxa have followed the autecological model in which one or a few cultured isolates are taken to be representative of the response and diversity in natural populations. The fallacy of this approach was shown by Wood and Leatham (1992), who documented in their review significant variation in response among all strains tested within a given microalgal species for a wide variety of responses to environmental stressors. Thus, this acceptance of only a few isolates or strains as representative of a species has seriously hampered our understanding of the relationship between genotypic and phenotypic variation in the microalgae, including HAB taxa, and how this interaction provides the basis for adaptation and ecosystem resilience.

Advanced studies of the genetic composition and gene expression potential of various HAB taxa – the functional ecogenomic approach – can now provide insights into the capacity for survival and adaptation at both the species and population level. High-throughput sequencing (e.g., next-generation 454-pyrosequencing) coupled with bioinformatics platforms offer the capacity for sequencing and annotation of entire genomes of a wide spectrum of eukaryotic microalgae. For HAB species, several such initiatives are underway or essentially completed, for example, for the occasionally toxigenic diatom *Pseudo-nitzschia pungens* (Armbrust, 2009), and more are in the pipeline. Although the enormous genome size

(from 3000 to 215,000 MB) and complexity of the dinoflagellates remains a challenge for whole genome sequencing. *Heterocapsa circularisquama* is presently being sequenced. This dinoflagellate was chosen because the genome of the virus that kills it has been sequenced. Alternatively, limited genomic investigations based on expressed sequence tags have already contributed critical insights into the genome of several HAB species (Yang *et al.*, 2010; Jaeckisch *et al.*, 2011), including the diversity of genes associated putatively with bloom dynamics and toxin biosynthesis. Attempts to model HAB dynamics must take into account the inherent cryptic diversity within and among populations, particularly with respect to toxigenesis and growth regulatory genes. New molecular probe technologies offer the ability to detect and identify genotypic variation within HAB species and populations, in some cases at the individual cell level. When implemented on deployable sensor platforms, this opens the possibility for near-real-time assessment of shifts in biodiversity and gene frequency and expression in natural HAB populations, even over seasonal and annual bloom cycles.

Acknowledgments

This work was supported in part by a grant from the EU FP7 201724 MIDTAL to LKM. The contribution of ADC from Alfred Wegener Institute was provided via the Helmholtz Society Programme on Earth and Environment as part of the Coast Topic (WP2) on Integrating Evolutionary Ecology into Coastal and Shelf Seas Processes.

Biodiversity in Plant Breeding

Irwin L. Goldman, University of Wisconsin-Madison, Madison, WI, USA

Published by Elsevier Inc.

Glossary

Commodification The act of making something a commodity; or a traded item in the marketplace that is not differentiated from other similar types. An example of an agricultural commodity is Number 2 Yellow Corn, which has certain market characteristics and can be produced by many different cultivars of corn.

Cultivar Literally “cultivated variety,” or named entity developed by plant breeders and used by farmers to plant a crop.

Genetic variation Differences within and/or among organisms that are due to genetic causes.

Genetically modified organism An organism produced through introduction of a transgene or transgenes, most often by means of biotechnology.

Genotype The genetic makeup of an organism.

Landrace Broadly adapted population used by farmers in a specific geographic region. Often developed by farmers and often possesses substantial variation compared to modern cultivars.

Plant breeding The systematic process of genetic improvement of plants for food and agricultural uses.

Trait A quality or characteristic that an organism may possess through inheritance.

Transgene/transgenic Possessing a gene or genes that were transferred from another organism, most often by means of biotechnology.

Variety Synonymous with cultivar.

Don Duvick stated that “the goal of crop agriculture is to reduce biodiversity (biodiversity refers to the range of organisms present in the environment, and genetic diversity refers to the variation within and among those organisms that is due to genes) in favor of increased and easily accessible food supplies” (Duvick, 2007). Indeed, modern agriculture itself is characterized by ongoing attempts to minimize the number of species cultivated or raised, along with their attendant pathogens and pests, while maximizing the yield of food and fiber. For example, a modern Midwestern US farm may possess only a few major species such as corn, soybean, wheat, or alfalfa, in contrast to a much larger species diversity on the same farm that would have included dairy cattle, swine, sheep, poultry, vegetables, herbs, and other grains prior to the middle of the twentieth century.

Industrialization of crops such as corn during the twentieth century has provided opportunities to produce many more products from the same raw material, including feeds, oils, starches, food additives, fabrics, packaging materials, sweeteners, and fuels. Plant breeding (plant breeding is the systematic process of genetic improvement of plants for food and agricultural uses) has played a critical role in this process by producing improved cultivars capable of multiple end uses. Commodification of the raw product reduces prices for consumers and processors and makes more goods and services available with less cost to the public. Government price support programs have fostered cropping systems that focus on fewer, major crop species and their supporting technologies, such as herbicides, insecticides, and fertilizers. This in turn has kept commodity prices low and made food prices a much smaller share of the US family budget than in many other countries worldwide. While the efficiency of this approach is one of the hallmarks of US agriculture, the concomitant reduction in biodiversity on the farm is a similarly defining aspect of our modern farming system.

But has this reduction in biodiversity been important for US agriculture, and is it important for our future? Has this reduction in biodiversity also caused important changes in genetic diversity? By focusing our goals on fewer refined species throughout the process of domestication and breeding, humans have substantially reduced the available biodiversity within these species. This in turn has led to cases of genetic bottlenecks, genetic vulnerability, and crop failures. But it has also led to huge increases in agricultural productivity; and interestingly, some breeding efforts have also reversed genetic bottlenecks, resulting in increases in phenotypic diversity of useful traits. Modern biotechnology has both increased genetic diversity through identification of useful allelic variants and reduced genetic diversity through the widespread deployment of single transgenes in major commodity crops across many countries. During all of agriculture’s history, introgression of genes from wild and feral species has continued to modify domesticated plants and bring both wanted and unwanted genetic diversity into the mix.

The US public and private sectors have each contributed in many ways to both reductions and expansions of genetic diversity in crop breeding, fueling the growth of modern scientific breeding through the development of theory and practice, and fostering the growth of agricultural production and food processing technologies. Today, the public sector focuses more on the preservation and enhancement of genetic diversity, through gene banks and prebreeding activities, while the private sector focuses primarily on the development of elite cultivars for crop production.

Since the 1980s, many countries have adopted a legal framework that supports the protection of intellectual property rights for crop germplasm. This further fueled the growth of the agricultural private sector, which today dominates crop breeding activities on a global scale. In addition, the global focus on germplasm rights has resulted in treaties that

emphasize bilateral agreements between countries for germplasm exchange. While these treaties may create new remunerative relationships between countries, they may also reduce the trade in genetic resources and reduce biodiversity.

The plant breeding landscape may thus be characterized by many fluxes of biodiversity in different directions, some of which are in tandem, some of which are competing, and some of which are entirely independent of each other. The paradoxical nature of these fluxes encompasses (1) breeders both reducing and enhancing diversity for various traits, (2) biotechnologists and breeders incorporating novel allelic variants in the form of transgenes or other unique variants into crop cultivars and deploying these cultivars over vast acreages of agricultural land, (3) consumer demand driving reductions in diversity and increases in uniform commodities, (4) government programs sustaining diversity levels by supporting current major crops and their cultivation systems, (5) a legal framework that supports intellectual property rights for crop germplasm and mandates bilateral agreements between countries for future germplasm exchange, (6) preservation, maintenance, and enhancement of genetic diversity through public gene and seed banks, and (7) natural and artificially induced gene transfer from wild relatives. All of these elements contribute to the dynamic patterns found in crop genomes and on farmer's fields. The goal of this article is to explain and highlight the nature of these fluxes in crop biodiversity and to characterize their importance and future in plant breeding terms.

Modern Scientific Plant Breeding

Although plant breeding dates to the beginnings of agriculture, modern scientific breeding dates back only a little more than 100 years. Mendel's work describing the fundamentals of heredity was published in 1865 but lay dormant until 1900, when it was more widely publicized in Europe. After 1900, the genetic revolution that ensued had a strong impact on plant breeding. Although breeders had unknowingly been using many procedures that exploited genetic variation via crossing and selection in the nineteenth century, the merging of quantitative genetic theory with Mendelian heredity provided a clear foundation for the modern science to begin (Janick and Goldman, 2003).

For cross-pollinated crops, the first half of this period was characterized by refinement of landraces and open-pollinated populations and substantial efforts to produce inbred lines from these populations. An important element of this early work was the recognition that crops have a distinct center or centers of origin, which correspond to their centers of diversity. These ideas were first advanced by Nicolai Vavilov, a Russian botanist who was also one of the world's leading geneticists (Crow, 1993). Through the work of Vavilov, plant breeders became aware of the need to collect, preserve, and study landraces and other germplasm from the various centers of origin of their crop species. This in turn opened up opportunities for exploration and trade of germplasm resources specifically for the purpose of breeding.

Once plant breeders had evaluated landraces and open pollinated populations for useful traits, and sufficient inbreeding had been accomplished, inbred lines were crossed

into hybrid combinations to form productive F1 hybrids. By the 1970s, F1 hybrids could be found not only in agronomic crops like corn, but also in horticultural crops such as onions and carrots, as well as dozens of ornamental species. However, the drive toward productive F1 hybrids was part of the reason that diversity issues aroused great concern among plant scientists and the general public.

Perhaps the most defining twentieth century moment in crop genetic diversity occurred in 1970 when Southern corn leaf blight, caused by *Helminthosporium maydis* (Nisik and Miyake) (now called *Cochliobolus heterostrophus* (Drechs.) Drechs), caused widespread destruction of the US corn crop. A majority of the F1 hybrid corn in the US contained "Texas" sterile cytoplasm for the purpose of making F1 hybrids, and the Texas cytoplasm was coincidentally susceptible to this pathogen. The genetic uniformity of approximately 80% of the US corn crop stimulated government and private sector scientists to look for alternatives, and spawned numerous commissions to study the genetic variability of US crops. One of the most important landmarks to result from that work was a report from the [National Research Council \(1972\)](#) that highlighted the need for genetic diversity in our crops (National Academy of Sciences, 1972). This report described that the key lesson of the 1970 epidemic was that genetic uniformity was the basis of crop vulnerability. The Committee on Genetic Vulnerability of Major Crops who authored the report found that most major crops were "impressively uniform genetically and impressively vulnerable." Importantly, the Committee also found that the uniformity derived from "powerful economic and legislative forces," and that the situation posed national challenges that must be addressed. One of their recommendations was a national facility for continuously maintaining gene pools at home and abroad, which today is carried out by the National Plant Germplasm System. The fact that the Committee identified the importance of "economic and legislative forces" 40 years ago underscores one of the key messages of this article: fluxes affecting biodiversity in plant breeding are many, varied, and complex.

In the intervening 40 years since the National Academy of Sciences report, genetic resources and genetic variation have been important foundation concepts in plant breeding. Scientific societies such as the Crop Science Society of America created space for study of these issues, and in 1990 included a section called Plant Genetic Resources in their chapter. Scientific journals such as *Crop Science* began to devote separate sections to genetic resources, highlighting the importance of this area to plant improvement and production agriculture. Numerous studies and publications have highlighted the importance of identifying, preserving, and maintaining crop genetic diversity for the future of food and agriculture, and public funding has been directed toward increasing global efforts in these areas. In contrast to the earlier part of the twentieth century, plant breeders today possess a high level of awareness and readiness with respect to the maintenance of genetic diversity.

It is, however, still important to note that the replacement of older cultivars with newer, higher-performing ones is a hallmark of successful plant breeding. Historical descriptions of crop breeding regularly mention the disappearance of older cultivars and the replacement of such favorites by newer, high performing varieties. Such disappearance can result in a loss of

biodiversity. In some ways, the rapid progress of modern plant breeding is responsible for the parallel growth in trade of heirloom seeds and for the activities of organizations such as Seed Savers Exchange (Decorah, Iowa). These efforts include elements of gene conservation and preservation, a great appreciation for classic and familiar cultivars, and social commentary on modern agriculture. Kloppenburg (2004) eloquently described how commercialization of technologies such as F1 hybrid seed have contributed to reduced diversity and further commodification of our crops (Figure 1). He also points out how current efforts to combat these trends have flowered in recent decades, providing avenues for resurrecting the public aspects of crop breeding. Despite this, examples of the homogenization of crop germplasm may be found among certain industrial crops where strict standards are required by new cultivars. The American Malting Barley Association provides a list of criteria that must be satisfied for new barley cultivars (Figure 2), suggesting the possibility of narrowing the germplasm pool if those criteria are met. However, there is contradictory evidence (see Does Variation Become Reduced Through Breeding?) on whether such focused breeding programs actually reduce genetic diversity (Rasmusson and Phillips, 1997).

Does Variation Become Reduced Through Breeding?

A common refrain about modern plant breeding is the concern about its potential to reduce genetic diversity by increasing selection pressure on the uniform conditions typical of modern agriculture. Plant breeding is an evolutionary process that results in changes in the genetic makeup of plant populations. Some changes in diversity are to be expected, but patterns of change have not always been consistent, and it is not accurate to say that plant breeding is unidirectional with respect to diversity. Breeders incorporate or make use of many of the same elements of natural selection in the core aspects of breeding programs, such as fecundity, heritable variation, and differential reproduction and survival. Variation is both created and destroyed in breeding populations, and one of the key goals of breeders is to manage this variation to the betterment of crop cultivars. An example of the creation of

variation is the recombination that takes place in thousands of meiotic events as a breeder makes crosses between strains in a breeding program. This recombination generates thousands of new genetic combinations, some or all of which may never have previously been produced in any breeding program (Figures 3 and 4). It is also possible that some of these recombination events will result in transgressive segregation, resulting in individuals that fall outside of the mean values of parental traits. These new genetic combinations may be planted and evaluated by the breeder. A breeder evaluating these recombinant populations may choose an individual or

individuals at the tail end of the population and discard the rest. Variation is therefore both created and discarded in each breeding cycle.

Many examples suggest a loss of genetic variation and allelic diversity through concerted breeding efforts, but a substantial body of work demonstrates that the opposite is also possible. One of the most famous selection experiments of the twentieth century is the Illinois Long Term Selection experiment conducted with maize at the University of Illinois in Urbana (Figure 5). The origins of the experiment were influenced primarily by work conducted in France by early breeders of the fodder beet (Hopkins, 1899; Troyer, 1996; Dudley and Lambert, 1992), and the early focus of this experiment was modification of the corn kernel's chemical makeup. The experiment was conceived by Cyril Hopkins, a chemist. The goal of his project was based on "Darwin's principle of selection," which was employed to modify the chemical composition of the corn kernel (Goldman, 2004). Perhaps the most unusual result of this experiment is the fact that genetic variation remains even after more than 100 generations of selection in a closed population. The observation of continuing gain from selection despite what would appear to be large reductions in genetic variance and large increases in inbreeding that have

Figure 5 Queen Anne's Lace, also known as wild carrot, is a ubiquitous weed that may have unique genes for crop improvement.

accompanied more than 100 generations of selection is startling. The paradox of this long term selection experiment is the cause for celebration among plant breeders, who often see it in terms of a limitless source of variation for selection and a reason they can continue to make gain from selection in breeding populations (Goldman, 2004). While it is possible that maize is unique among crop plants for the flexibility of its genome, these results suggest that genetic diversity may not be fully understood, even in the context of closed breeding populations studied for centuries.

Rasmusson and Phillips (1997) described a paradox involving continued plant breeding progress for barley (*Hordeum vulgare* L.) malting traits despite what appeared to be a continually narrowing genetic base for the crop. The authors suggested *de novo* variation in the form of transposable elements, transcription factors, intragenic recombination, epigenetic phenomena, and the like, may be arising during the selection process, thereby creating variation on which plant breeders can select. While our understanding of such phenomena in the context of breeding populations is currently limited, it is likely that research investments in this area will yield important insights into the flux of genetic diversity during the breeding process. If, like in the case of the Illinois Long Term Selection experiment, breeding populations are capable of producing substantial and useful *de novo* variation while under selection, the apparent loss of biodiversity through narrow breeding objectives may be mitigated. However, much more remains to be learned on this topic before plant breeders can claim *de novo* variation as a cornerstone of their breeding programs.

Huang *et al.* (2007) investigated whether modern winter wheat (*Triticum aestivum* L.) breeding in Europe has resulted in a loss of genetic diversity within and among wheat varieties. They evaluated 511 widely grown varieties from Central and Northern Europe using microsatellite markers. By far, the largest source of variance in their study was the variance among

varieties within decadal groups between the period 1945 and 2000. Only a small share of the variance was due to differences between the decadal groups. Their analysis suggested that while allelic changes have occurred in modern plant breeding, no apparent loss of genetic diversity or allele number was detected in this collection of varieties. Fu *et al.* (2003) studied a similar question in oats (*Avena sativa* L.) and found certain specific marker alleles that were reduced in diversity from 1886 to 2001, but that average genetic diversity across 96 Canadian oat cultivars as described by these markers did not decrease in a systematic fashion. Fu and Somers (2009) examined genetic diversity in wheat cultivars released from 1845 to 2004 using 370 simple sequence repeat markers. These workers found allelic reductions in every part of the wheat genome, with significant reduction beginning in the 1930s. While they concluded that the study provided clear evidence for reductions in genetic diversity through breeding, it is not clear to what extent these simple sequence repeat markers represent a loss of useful genetic variation for crop improvement. Indeed, many molecular markers are neutral to phenotype and thus it is difficult to extrapolate from such markers to phenotype. It is, however, important to note that the allelic reduction noted was substantial and genome-wide, suggesting broad patterns in the wheat genome that are worthy of further study.

An explosion of interest in certain crops has meant a corresponding increase in the available genetic resources for plant breeders. This *et al.* (2006) indicated that the genomic resources available to the grape (*Vitis vinifera* L.) research community have increased substantially since 2001, partly because of the renewed interest in this crop. Sexual recombination and asexual reproduction have expanded and diversified grape germplasm collections (This *et al.*, 2006), and more germplasm is currently cataloged and available to breeders than ever before. In this way, consumer demand for grape products such as wine, table grapes, and raisins has resulted in increased investment in grape germplasm collections and breeding efforts, which in turn means more available grape diversity. Public and commercial interests have the potential to drive diversification and expansion of breeding programs. By the same token, crops for which consumer demand has weakened may find correspondingly less breeding activity. Table beet (*Beta vulgaris* L.), a minor crop in the US, is no longer bred by most US vegetable seed companies and is represented in only one public US breeding program (Goldman and Navazio, 2002). Genetic resources for this crop may not be as diversified and well-characterized as a result, and the total amount of diversity found decades ago may not be able to be preserved or maintained.

Genetic Bottlenecks

A feature of most domesticated plants is a reduction in genetic diversity following domestication (Gepts, 2004). Many studies using molecular markers or gene sequence information have demonstrated reductions in diversity during and after domestication. However, some studies based on phenotypic data have shown increases in phenotypic diversity following domestication. One of the central theses of Darwin's *Variation in Plants and Animals Under Domestication* (Darwin, 1868) was

that variation is created and preserved in those plant organs on which humans depend. Seeds of *Phaseolus vulgaris* L., for example, have highly varied seed coat patterns, likely because variants have been observed, collected, and preserved by humans. The same is true for shape and color of potato tubers. Traits with very strong selective advantage, such as those of interest to humans for food production, are likely to be preserved under domestication. Molecular markers are often neutral and may not be selectively advantageous. It is therefore difficult to predict the degree to which they would survive under domestication. In general, domestication events seem to be associated with a loss of diversity, but intense selection following domestication appears to be responsible for increasing phenotypic diversity. The bottleneck through which many of our crop species has come has itself suggested breeding strategies that seem to show some promise.

Genes from related wild species have been promising for traits like disease and pest resistance, but breeders have historically shied away from them for productivity traits. This is primarily because wild species chromosome segments also may carry unfavorable alleles that can dramatically alter crop productivity. Tanksley and McCouch (1997) examined wild rice species accessions and crossed them to elite inbred lines. They found increases in yield from early-generation progeny of these crosses, suggesting wild species had much more to contribute in terms of productivity traits than previously thought. Gur and Zamir (2004) described useful and productive variation from wild species of tomato that was capable of increasing yield over elite commercial cultivars while using less water. Interestingly, they describe the variation in these wild species as "unused," which suggests that modern plant breeding has left useful variation in its germplasm banks, waiting to be incorporated into cultivars. Zamir and colleagues also created an introgression population of *Solanum pennellii* chromosome segments in an elite *Lycopersicon esculentum* background (Eshed and Zamir, 1995). Some of these introgression lines exhibited higher yield than elite genotypes, suggesting great promise for wild species chromosome segments. Johal *et al.* (2008) have recently described a technique known as mutant-assisted gene identification and characterization (MAGIC) that makes use of mutants or variants in a trait of interest to identify novel variants for the trait. This technique, and others like it, has the potential to identify useful natural variation that can be incorporated into breeding populations (Figure 6). Increasingly, breeders have become interested again in variation that is natural and the result of millennia of selection in agricultural conditions (Zamir, 2008). Studies such as these have fueled renewed interest in gene banks and wild species, not only as a source of important disease and pest resistant characters, but also as a source for productivity traits. In addition, the incorporation of wild species genes into elite inbred lines and cultivars has resulted in greater diversity in breeding populations. This is yet another example of how breeding activities can contribute to increasing diversity in crop germplasm.

Gene Pool Concepts

Crop genetic resources are the genes and gene combinations available for crop improvement. For the past 40 years, since

Figure 6 Response to selection for oil and protein in maize in the Illinois Long Term Selection Experiment (Reproduced from Dudley JW and Lambert RJ (1992) *Ninety generations of selection for oil and protein in maize. Maydica* 37: 1–7.).

the work of Harlan (1971) and Harlan and de Wet (1971), crop genetic resources have been categorized in three gene pools. Gene Pool I included the crop and its wild progenitors, and is typically consistent with the biological species concept (Gepts, 2006). Crossing should be successful among species in this gene pool. Gene Pools II and III reflect increasing genetic distance away from the crop species, respectively, with crosses much more difficult, if not impossible, to make. Occasionally, such crosses require the aid of techniques such as embryo rescue and tissue culture. Gepts has also suggested (2002, 2006) the need for enumeration of a Gene Pool IV that reflects the genetic diversity that can now be accessed through biotechnology. Some biotechnological approaches make it possible to clone nucleic acids from any organism and insert them into a vector that can be introduced into a plant. This makes genetic resources available for crop improvement that were not previously possible to access. Interestingly, Gene Pool IV may be accessed by any of the other three Gene pools, though it will likely require molecular techniques in each case. Gepts (2006) pointed out that while one of the contributions of biotechnology to plant breeding should be a broadening of the gene pool and resulting biodiversity increases, it has thus far had a limited role because of the limited number of genes thus far available and our lack of understanding about their interaction with the plant genome.

It should also be mentioned that farmers themselves are critical curators of genetic diversity for current and future plant breeding efforts. While many US farmers may purchase seed from companies each year, farmers in the developing world collect, curate, and maintain genetic diversity for themselves

and their neighbors. This is true for many crops, including major industrial crops such as corn, where farmers in the developing world still grow the majority of the world's acreage and manage the seed resources for the crop. Pearl millet (*Pennisetum glaucum* L.) landraces are grown and maintained by farmers throughout the world. A study by vom Brocke *et al.* (2003) examined the management practices of farmers in Rajasthan, India with respect to pearl millet germplasm. These workers found that crop management practices and seed systems practiced by farmers in the region were the primary determinants of genetic diversity patterns of the landraces and cultivars grown. Some regions exhibited landraces that possessed more intravillage variation while other regions showed landraces with more intervillage variation, depending on seed practices. These practices are fundamental plant breeding practices, and as such are important regulators of genetic diversity in crop germplasm.

Duvick (2007) described genetic diversity in place and genetic diversity in time as ways that farmers and agriculturists have preserved biodiversity. Genetic diversity in place is a type of spatial diversity, where farmers plant several kinds of crops or several varieties of a crop to insure some of them would survive poor weather or pests. In general, farmers still practice the use of genetic diversity in place by planting different cultivars of the same crop in the same field with the hope that some will do well regardless of the environmental conditions. Other farmers practice a more dramatic form of diversity in place by growing many species in the same field, or by intercropping two or more different species in the same field. The use of multiple species of crop in the same field is sometimes

referred to as a polyculture. The classic Central and South American example of this type of intercropping is maize and beans grown in the same hill, where the beans twine around the maize plant for support. Native Americans also combined these plantings with squash, increasing native diversity levels. Another form of increased genetic diversity in a cultivar is the multiline, which is essentially a mechanical mixture of individual lines, each bred to have a specific trait. An example of such a cultivar would be one bred to combine resistance to individual races of a pathogen by combining inbred lines, each carrying a resistance allele.

Genetic diversity in time is based on the fact that for most crops, seed planted in any given year is not genetically identical to the seed produced by the crop in a subsequent year (Duvick, 2007). This constant shifting of genotypes, characteristic of the process of evolution via natural selection, means that cultivars exhibit changes in their genetic makeup over time simply through the process of cultivation. Duvick wisely observed that “the sequential genetic changes represented continuing adaptation to prevailing constraints to yield.”

Many crop species now have a number of resources attached to them with respect to germplasm preservation. For example, key crop species are often preserved in *ex situ* and *in situ* collections worldwide. Examples of the former include gene banks and seed banks, while the latter includes biodiversity preserves that attempt to conserve germplasm as a living organism in its habitat. Care is taken to include

germplasm from various Gene Pools in these collections, and many collections have curators whose specialty involves characterization and preservation of the germplasm. Some of the collections include “core collections,” which are meant to capture a full range of genetic diversity in a limited number of germplasm accessions. These accessions then can be used by researchers and breeders to evaluate particular traits, such as disease or pest resistance, and conclusions can be drawn from this sample that may be extrapolated to the entire collection. Breeders maintain their own collections of germplasm for use in current and future situations, along with segregating populations derived from crosses between Gene Pools. Some crops may also have genetic stock centers maintained by public funds that allow for the creation, maintenance, and study of unique genetic materials for research and breeding. All of these structures help preserve biodiversity in plant breeding and ensure a future where genetic resources will be available (Figure 7). In some cases, these structures increase biodiversity and foster a climate where new genetic combinations can be created and studied.

Exploration and Trade

It is worth noting that the voyage of Columbus was to find a route to Asia in order to acquire spices for Europe. His trips led to what first became known in 1972 as the “Columbian

Exchange" (Crosby, 2003), where plant species and other organisms moved between Europe and the Americas. This single event, or series of events, led to explosive growth in crop genetic resources for both Europe and the Americas, and diversified the genetic resources in both continents. It also had the effect of homogenizing agricultural landscapes on the two continents, for example, by increasing the growth of corn in Europe and the growth of wheat in the Americas. An individual's diet in each country may have become more diversified, but agricultural land in both continents may have come under more similar patterns of use. The scale is important. Locally, regions were diversified and biodiversity increased. Globally, regions became more similar. Some would argue that the crops were successful in getting humans to spread them even farther and prepare landscapes for them to thrive (Pollan, 2006). Regardless, exploration and trade shuffled genetic resources between localities that had never seen them before, while also making some aspects of crop agriculture more uniform. This example highlights the push and pull of biodiversity, reinforcing the notion of contrasting fluxes operating in a complex landscape.

The US government became actively involved in plant and seed acquisition in the nineteenth century and began building a national plant germplasm system, which today is managed by the US Department of Agriculture and holds many thousands of accessions of hundreds of species. The US Department of Agriculture still employs scientists whose primary role is to collect and characterize wild crop relatives. While substantial genetic resources are held in this repository and made freely available upon request, humans rely on only approximately 100–150 crop species for their survival, and of these, only approximately 15 make up the bulk of calories in the US diet. One could argue that biodiversity is preserved by the existence of seed banks such as the National Seed Storage Laboratory in Fort Collins, Colorado. But one could also argue that biodiversity is threatened because the existence of some of these species is only as a static entry in a germplasm bank and not as a growing and evolving species in either agriculture or nature. Regardless, plant breeding does and will continue to depend on these genetic resources for its future. These accessions make up the raw material for many of the day-to-day activities of plant breeders. The simple fact that they are preserved secures a measure of biodiversity for the planet and provides hope for future breeding efforts.

The Legal Framework

Two treaties cover the legal framework for crop biodiversity: the UN convention on Biological Diversity, and the International Treaty on Plant Genetic Resources for Food and Agriculture. The former covers genetic diversity in animals, plants, and microbes, while the latter focuses on global food security. The Convention on Biological Diversity moves away from the concept of germplasm and genetic diversity as the common heritage of humankind, and focuses instead on the development of bilateral agreements that include benefit sharing among countries that hold or desire genetic resources. The US has not ratified the Convention on Biological Diversity, but has on certain occasions participated in bilateral

agreements with other countries for germplasm exchange. In the main, however, the US National Plant Germplasm System has a fundamental goal to make germplasm freely available to any and all requestors; a situation that is almost unique among world germplasm banks. The International Treaty on Plant Genetic Resources for Food and Agriculture focuses solely on plant genetic resources used to produce food, and covers 64 crops. This treaty contains a pool of genetic resources that are available freely to those countries that sign on and agree to use the material only for research and plant breeding activities for the benefit of food and agriculture.

Patents for plant germplasm have also played an important role in the diversity landscape for the past 25 years. Although prior to 1980, the only patents available for plant germplasm were for asexually propagated species, changes in US law allowed for cultivars, genes, plant breeding processes, and associated technologies to be patented. In some cases, utility patents were issued that covered broad-based breeding procedures and the cultivars they produced. In the 1970s, the Plant Variety Protection act was adopted, which led to increased opportunity for protection of seed-propagated crop species. Importantly, the Plant Variety Protection Act did not restrict breeding with cultivars protected in this way, whereas cultivars that were patented could not be used before obtaining a license from the owner.

The implications of these two treaties and the trend toward plant patents with respect to biodiversity are important for plant breeding. In a previous era, the concept that germplasm was the common heritage of humankind prevailed, and germplasm was exchanged freely among plant breeders. Public sector plant breeders often adopted "codes of ethics" or protocols that provided for attribution, when appropriate, for the use of germplasm from other breeding programs. However, free exchange was the rule rather than the exception. Since the 1980s, public institutions with breeding programs have sought to secure revenues for germplasm developed by their scientists. Initially, this was accomplished by individual breeders who sought to bring royalties for germplasm directly back to their breeding programs. But with cutbacks in public funding and a national trend toward identifying new revenue sources for public institutions in the 1990s, many sought to formalize contractual agreements for germplasm whereby licensees or purchasers would pay royalties to the technology transfer arm of the institution. Many institutions sought legal protection for plant germplasm, in the same way a private company would normally do so. This aspect of technology transfer is only approximately 20 years old in the US and it may be too early to tell if it has been a successful model. Anecdotally, however, there is some evidence that it has reduced germplasm exchange among breeding programs because of protective clauses in germplasm agreements. In contrast, there is also some evidence that royalties generated have helped support public breeding programs, which otherwise may have folded due to lack of public funding. The paradox inherent in this institutional solution is obvious: public breeding programs in danger of becoming extinct rely more and more on royalty generation, which has the potential to further reduce germplasm exchange, limit breeding activities, and thereby impinge on genetic gain. Recently, some have suggested open-source models of germplasm release similar to approaches used by the computer

software industry (Open Plant Breeding Foundation, website). Such approaches have the potential to reaffirm the public nature of public breeding programs, but the issue of financial support for such programs is still a concern.

Commodity Agriculture and Biodiversity

One of the most remarkable and successful features of US agriculture is the way animals and crops have become commodified, increasing the efficiency of the market, reducing costs for processors and consumers, and hedging natural and human-caused risks inherent in agriculture. Commodity agriculture has also spawned markets for speculators, who link farmers with end-users in an attempt to profit from changes in commodity prices. One could argue that consumers ultimately benefit from this arrangement through lower prices and more reliable supply of the commodities they need. However, commodity agriculture favors uniformity of product and therefore may impinge on crop diversity. For example, the very nature of commodity corn means that any particular corn kernel is not differentiated from any other corn kernel, and their equal treatment leads the crop itself to be considered monolithic with respect to the market. Because many types of commodity corn are not identity preserved (there are certainly types that are, including corn for ethanol and certain types of animal feed), there is no corresponding incentive for breeders, farmers, or processors to demand diversity. In fact, this system provides incentive for field homogeneity. While one might argue that breeders must still develop ever higher-performing cultivars and thereby increase new genetic diversity into the mix, it is also true that the drive toward sameness could have an impact on genetic diversity. As our commodity markets have become global, this situation promises more homogeneity with respect to crop diversity in the future.

Green Revolution Genes and Biotechnology

Worldwide food production on a per capita basis is higher today than it was 50 years ago (Trewavas, 2001). Plant breeding and its associated technologies have played a significant role in these increases. One example of this was the introduction of dwarfing genes in both wheat and rice that led to the Green Revolution. The Green Revolution refers to technological change in agriculture that occurred in the developing world during the 1960s. The powerful combination of a shift in the harvest index by partitioning more energy into grain production and less to overall biomass, along with significant increases in fertilizers and pesticides, allowed for massive increases in food production in the developing world. The father of the Green Revolution was Normal Borlaug, the only plant breeder to have received a Nobel Prize for Peace for his work on improving world agriculture. The genes used by Borlaug that were responsible for producing dwarf strains of wheat and rice were later discovered to interfere with the signal transduction pathway of gibberellic acid, an important growth hormone (Hedden, 2003). The dwarfing effect produced the dramatic change in harvest index and biomass partitioning that drove increased grain yields.

The wheat dwarfing genes responsible for these changes, *Rht-B1b* and *Rht-D1b*, originated in Japan and were bred into American cultivars in the middle of the twentieth century. Today, these genes are present in approximately 70% of commercial wheat cultivars worldwide. Various alleles of a single recessive gene, *sd1*, are responsible for the semidwarf phenotypes of rice, which have also been used to make dramatic improvements in rice yields around the world. The *sd1* alleles also interfere with gibberellic acid biosynthesis, making modification of this growth hormone a key step toward increasing crop yields during the twentieth century.

From the point of view of biodiversity, one could argue that the widespread deployment of single genes such as *sd1* or *Rht-B1b* in the majority of rice or wheat cultivars grown across the world means that biodiversity is reduced. The homogeneity associated with cultivars carrying these genes may seem to be limited to single genes, but one may also imagine that other genes in the wheat and rice genomes have been similarly selected to perform well in concert with the dwarfing genes. This in turn may unwittingly lead to more crop uniformity. However, one could also argue that the use of these genes has fueled tremendous expansion of these crops throughout the world, increasing the number and scope of breeding programs worldwide, and increasing the number of environments in which these crops can be successfully grown. As breeders incorporate these genes into new genetic backgrounds, additional diversity will be generated. Green Revolution genes may therefore serve as an example of a reduction in biodiversity of crop cultivars as well as a stimulus for generated new diversity and adaptation via breeding.

Biotechnological innovations have revolutionized plant breeding in the past 30 years. Among the most controversial and powerful of these innovations has been the development of transgenic, or genetically modified, crops. The advent of this technology followed the successful development of many workhorse tools such as gene cloning, plant transformation, regeneration, and suitable vectors for hosting genes of interest. By the late 1980s, crop cultivars carrying transgenes were being tested, and the first commercially available transgenic crop was released in 1993. By 1995, substantial acreage in the US was devoted to transgenic corn and soybean for herbicide and insect resistance. The extremely rapid adoption of these technologies demonstrates their utility to farmers, processors, and consumers, though they are not entirely without controversy in the US. Still, the US marketplace shows no sign of slowing down with respect to the use of transgenic crops; however the use has been confined primarily to corn, soybean, cotton, and canola. Some transgenic squash is produced, as is some transgenic papaya, and both sugarbeet and alfalfa have recently been deregulated for use as transgenic crops in the US. Many transgenes have been inserted into a broad range of crop species in the context of research programs, but there is currently no sign of new transgenic crops entering the commercial marketplace other than the primary crops mentioned above (corn, soybean, cotton, and canola). Some consumers have expressed concerns about certain aspects of genetic modification, including the possibility of gene flow to wild or weedy relatives, the possibility of creating novel, allergenic proteins in transgenic species, and food safety aspects of transgenics, and a lengthy and at times rancorous debate has

ensued in the US and in Europe, where transgenic crops have only recently begun to appear.

Transgenic technology means that nucleic acids from any source may be added to the plant genome. In theory, this greatly expands the possibility of increasing crop biodiversity through the addition of genes from any organism with the potential to improve crops. Likewise, it is also the source of concern for many consumers, who see transgression of the species and kingdom boundaries as potentially problematic. It is important to note that the species and kingdom boundaries are occasionally transgressed in nature, and it is in exactly one such example of this transgression that transgenic crops were originally produced: the soil bacterium *Agrobacterium tumefaciens*, which normally infects plant roots and transfers its nucleic acids to the host. From a biodiversity point of view, transgenic manipulation has the potential to expand biodiversity through the addition of genes from plants that would not have been able to cross in nature or under controlled conditions. Earlier, the author cited Gepts' assertion that a Gene Pool IV should be identified, which would represent those genes found anywhere in nature that have the potential to improve crop genomes. Indeed, one of the most remarkable aspects of transgenic technology is the limitless nature of the possible gene combinations that could be created. So, from a biodiversity point of view, there is much potential for enhancement through this particular tool of plant breeding.

There is a high cost associated with the development and deployment of transgenes in modern agriculture, and that cost is frequently prohibitive for smaller-scale seed companies to develop transgenic cultivars. Larger companies may be able to afford licensing fees, which reach into the millions of dollars, in order to license and obtain transgenes that can then be incorporated into their cultivars. Over time, this situation has the potential to limit the number of entities able to make the investment to produce transgenic cultivars, and may therefore reduce genetic diversity in crop germplasm as a result. In addition, as described above (*see* Green Revolution Genes and Biotechnology) for genes associated with the Green Revolution wheats and rices, the widespread deployment of single genes over millions of agricultural acres both expands the reach of these cultivars and simultaneously increases the genetic uniformity of elite crop cultivars. As transformation technology decreases in price, it may be possible to reverse this trend. However, it remains to be seen how much variation will be limited and how much will be expanded as a result of transgenic technologies.

An interesting recent development in the deployment of transgenes sheds some light on possible biodiversity scenarios for the future. Hutchison *et al.* (2010) evaluated the impact of transgenic maize carrying the *Bt* gene for resistance to European corn borer. Transgenic maize carrying the *Bt* gene had a suppressive effect on European corn borer in both *Bt* corn crops and in non*Bt* crops in neighboring fields. The suspected reason for the benefit to non*Bt* crops is that the female corn borers lay eggs indiscriminately in both *Bt* and non*Bt* crops. Thus, farmers may choose to grow nontransgenic maize, or a mixture of nontransgenic and transgenic maize, and be able to reap the benefits of the technology simply by being in close proximity to others who use the technology. The implications of these findings are of interest for the evolution of pest

resistance in particular and for biodiversity in general. If this "halo effect" phenomenon is generally true for transgenic crops or pest resistant crops, the evolution of pests may be slowed and the deployment of transgenes may be less pronounced than one might expect. Interestingly, Ronald (2011) describes studies where the planting of *Bt* crops has had the effect of increasing biodiversity. She cites the work of Marvier *et al.* (2007), who showed that nontarget invertebrates such as spiders, mites, and insects not targeted by *Bt* crops are more abundant in *Bt* corn and *Bt* cotton fields than in conventional fields managed with insecticides.

Summary

Despite the obvious reduction in genetic diversity that can be caused through focused plant breeding efforts, the author has endeavored to show that fluxes in biodiversity in plant breeding are not unidirectional. Rather, plant breeding has the potential to both decrease and increase biodiversity and genetic diversity depending on its objectives. Domestication and concerted breeding efforts have certainly reduced genetic diversity in some cases, but breeding has also expanded genetic diversity in other instances, and detailed analysis should be conducted on a crop-by-crop basis in order to assess, which fluxes in biodiversity have been most important. Today's plant breeding landscape also includes a complex legal framework that has the potential to inhibit germplasm exchange and reduce biodiversity. At the same time, public investments in gene banks and other preservation efforts have resulted in dramatic improvements in collecting biodiversity and hold great promise for future plant breeding. Biotechnology has the potential to result in enhanced genetic diversity of crop species, but deployment of transgenes on a landscape level is fraught with complex scientific and societal questions. At this point, biotechnological approaches have not made as much of an impact on biodiversity as they might in the future. The process of modern plant breeding has impacted crop biodiversity in many ways, not only through the genetic manipulation that is at the core of the breeding activity, but also by the surrounding economic, political, and legal forces that are a part of today's society. Plant breeders are fortunate to be aware of diversity issues in their daily work and have clearly made great strides to protect and enhance biodiversity. Our future food security will depend on their success in this area.

Glossary

Bundle sheath (BS) tissue A cell layer at the periphery of the vascular bundles in leaves. In C₄ plants, the reactions of the photosynthetic carbon reduction cycle are localized in this layer, in contrast to C₃ plants, where they occur in the mesophyll (M) tissue. In comparison to C₄ species, the BS cells of C₃ species are small, with few chloroplasts.

Kranz anatomy Specialized anatomy of the C₄ leaf in which the BS tissue is enlarged and enriched with chloroplasts, whereas the mesophyll is reduced in size and often forms a lighter green halo around the BS. This produces a wreath-like ('Kranz' in the original German) appearance.

Mesophyll (M) tissue Photosynthetic cells that are located between the arrays of vascular bundles and BS cells of a leaf. In C₄ plants, Phosphoenolpyruvate (PEP) carboxylase and pyruvate-phosphate dikinase are localized in the M tissue, while Rubisco is absent.

NUE Nitrogen-use efficiency, a measure of photosynthesis or growth relative to the nitrogen content of the leaves or plant.

Phosphoenolpyruvate carboxylase PEP carboxylase, the initial carboxylation enzyme in C₄ photosynthesis.

Photorespiration Biochemical process in which O₂ is assimilated during the oxygenation of RuBP, and CO₂ is given off in the metabolism of the products of RuBP oxygenation.

Rubisco Ribulose-1,5-bisphosphate carboxylase/oxygenase, the enzyme in all plants that catalyzes the formation of two phosphoglycerate molecules from RuBP and CO₂, and catalyzes the competing reaction of RuBP oxygenation.

WUE Water-use efficiency, a measure of the amount of photosynthesis or growth per unit of water lost in transpiration.

Introduction

In the past 35 million years, atmospheric CO₂ levels have declined from above 1000 ppm (ppm) to values below the current concentration of 390 ppm. During the peak of the ice age 20,000 years ago, atmospheric CO₂ levels were 180 ppm. The low CO₂ levels of recent geological time substantially impaired photosynthetic carbon gain in the Earth's flora, which relied on a biochemical mode of carbon assimilation termed C₃ photosynthesis. In response to carbon deficiencies brought about by low CO₂, multiple lineages of plants evolved a CO₂-concentrating mechanism termed C₄ photosynthesis. C₄ plants function with much greater efficiency than C₃ plants in warm environments, and contribute a much larger fraction to global primary productivity than their species numbers would indicate. The origin of C₄ photosynthesis also set in motion the evolutionary diversification of grazing and predatory guilds that created the diverse animal assemblages of grassland biomes of recent time. Today, C₄ plants are important contributors to biodiversity in tropical, subtropical, and warm-temperate habitats. C₄ plants currently play a major role in global agriculture and are the leading candidates for the next generation of bioenergy crops (Table 1). Much of the world's C₄ flora may be at risk in the future, because rising CO₂ and intense exploitation of C₄-dominated landscapes will reduce available habitat for native C₄ plants. A handful of invasive C₄ species will do well, however, as they are adapted to human disturbance. These species are already responsible for major reductions in biodiversity in tropical and subtropical ecosystems. In recognition of the significance of C₄

plants, this article provides an overview of C₄ photosynthesis and its contribution to global biodiversity.

What is C₄ Photosynthesis?

C₄ photosynthesis arose as an evolutionary modification of the preexisting C₃ photosynthetic pathway, which is used by approximately 250,000 plants. The C₄ pathway does not replace C₃ photosynthesis; instead, it complements the C₃ pathway, which is relocated to an interior compartment within leaves of C₄ plants. In C₃ plants, CO₂ is first fixed to the acceptor molecule ribulose-1,5, bisphosphate (RuBP), forming phosphoglycerate (PGA), a three-carbon, or C₃, organic acid (Figure 1). PGA is metabolized to sugars, starch, and RuBP by the C₃ photosynthetic carbon reduction (PCR) cycle, or Calvin–Benson cycle named after the team that discovered it. The PCR cycle completely occurs within the same cell, and hence all photosynthetic cells in C₃ plants conduct the same photosynthetic metabolism.

Photorespiration

The fixation of CO₂ by Rubisco and its conversion to starch and sugars using light-dependent energy is the primary source of photosynthetic carbon in all higher plants and algae. Rubisco, however, has a side reaction that is inhibitory for photosynthetic carbon gain. In the presence of O₂, Rubisco can oxygenate RuBP, creating one PGA molecule and one molecule of phosphoglycolate (PG), which has no value to the

Figure 1 Diagrammatic representation of the photosynthetic carbon reduction cycle and the photorespiratory cycle in C₃ plants.

Abbreviations: PG, phosphoglycolate; PGA, phosphoglyceric acid; RuBP, ribulose-1,5-bisphosphate. Reproduced from Sage RF (1999) *Why C₄ Plants?* In: Sage RF and Monson RK (eds.) *C₄ Plant Biology*, pp. 3–16. San Diego: Academic Press.

plant and is toxic if it accumulates in the cell (**Figure 1**). Plants metabolize PG back to PGA, but in the process 25% of the carbon in the pool of PG molecules is given off as CO₂. In addition, for every two RuBP oxygenation events, one adenosine triphosphate (ATP) and the equivalent of one nicotinamide adenine dinucleotide phosphate (NADPH) are required to convert PG to PGA, which can then be used to regenerate RuBP. The oxygenation of RuBP and subsequent PG metabolism are collectively termed photorespiration, because it involves the uptake of O₂ and release of CO₂, as observed in other respiratory processes. Photorespiration is a significant inhibition on C₃ photosynthesis in warm, low CO₂ environments, due to the energy use and loss of previously fixed CO₂

that occurs during PG metabolism. To overcome this inhibition, plants have evolved CO₂ concentrating mechanisms, the most significant of which is C₄ photosynthesis.

The C₄ Photosynthetic Pathway

In C₄ photosynthesis, leaf biochemistry and anatomy are modified from the C₃ pattern to concentrate CO₂ from an outer tissue or cellular compartment into an inner compartment in which Rubisco and the PCR cycle are localized (**Figure 2**). Concentration of CO₂ around Rubisco greatly reduces the rate of photorespiration and allows for greater, more efficient rates of photosynthesis. The outer compartment is commonly (but not always) the mesophyll (M) tissue in a leaf, whereas the inner compartment is either a distinct tissue layer in the middle of the leaf, or a distinct region within a single cell. CO₂ concentration occurs via the operation of a C₄ metabolic cycle, in which atmospheric CO₂ (in the form of bicarbonate) is first assimilated into four-carbon-organic acids in the outer compartment; these acids then move to the inner compartment where they are metabolized to release CO₂ (**Figure 2**). The term ‘C₄’ refers to the number of carbon molecules in the carboxylation product of the C₄ metabolic cycle.

C₄ photosynthesis has evolved dozens of times via the modification of preexisting enzymes and structures. Each version of the C₄ pathway is unique in some way. Variation is present in the enzymes and isoenzymes that have been co-opted for the C₄ metabolic cycle, in the tissue compartments used for CO₂ concentration, and in the cellular modifications to allow for efficient C₄ function. There are, for example, at least 22 distinct types of leaf anatomy in C₄ leaves. Because of

Figure 2 Diagrammatic representation of the C₄ photosynthetic cycle. The product of the PEP carboxylation reaction is oxaloacetic acid (OAA), which is converted into a transportable four carbon acid (C₄) that is either malic acid (NADP-ME type) or aspartic acid (NAD-ME and PCK subtypes). The decarboxylation reactions produce either pyruvic acid (PVA, produced by NADP-ME and NAD-ME) or PEP (produced by PEP carboxykinase). The PVA returns to the mesophyll chloroplasts, where it is converted to PEP using ATP. *Abbreviations:* CHL, chloroplast; triose-P, triose phosphate; PCR, photosynthetic carbon reduction cycle.

this variation, C₄ photosynthesis is best considered a syndrome, where dissimilar features are assembled to give rise to a common function. Although the elements making up the different versions of the C₄ pathway vary, in all cases there are common characteristics that delineate C₄ photosynthesis (Table 2).

C₄ Biochemistry

C₄ photosynthesis begins with the carboxylation of the three-carbon compound phosphoenolpyruvate (PEP) by PEP carboxylase, a cytosolic enzyme that is highly expressed in the M tissue of C₄ plants (Figure 2). PEP carboxylation is the only biochemical step common to all C₄ plants. The product of PEP carboxylation is the four-carbon organic acid oxaloacetate (OAA), which is rapidly converted into the organic acids malate or aspartate. These acids are then transported to the inner compartment where a decarboxylating enzyme breaks them down to CO₂ and either pyruvate (in most species) or PEP. There are three decarboxylases used in the different lineages of C₄ photosynthesis and these define the biochemical subtypes of C₄ photosynthesis. They are NADP-malic enzyme (which predominates in the NADP-ME subtype of C₄ photosynthesis), NAD-malic enzyme (which defines the NAD-ME subtype), and PEP carboxykinase (PCK) (which is predominant in the PCK subtype). NADP-malic enzyme is the most commonly used decarboxylase, being employed in about two-thirds of the C₄ evolutionary lineages, including both

Table 2 Requirements for C₄ photosynthesis

1. CO₂ fixation by PEP carboxylase to form four-carbon organic acids.
2. Coupling of photosynthetic energy (ATP, NADPH, or equivalents) to regenerate PEP.
3. An intermediate metabolite pool (generally organic or amino acids) to transport CO₂ from the compartment of PEP carboxylation to the compartment containing Rubisco and the decarboxylating enzymes.
4. A decarboxylating enzyme to release CO₂ from the intermediate metabolite pool.
5. A compartment in which to concentrate the released CO₂ around Rubisco.
6. A diffusion barrier to slow the loss of CO₂ from the site of CO₂ concentration.

Source: Modified from Leegood R (2002) C₄ photosynthesis: Principles of CO₂ concentration and prospects for its introduction into C₃ plants. *Journal of Experimental Botany* 53: 581–590.

monocots and dicots. NAD-ME also occurs in monocots and dicots and is the second most common type, being predominant in about a third of the C₄ lineages. PEP carboxykinase is the least used, being present in only four grass lineages. During catalysis, NADP-ME and NAD-ME release pyruvate and CO₂. PEP carboxykinase releases PEP and CO₂, but requires one ATP to drive the decarboxylation reaction. The released CO₂ accumulates to concentrations 10 times or more above current atmospheric value, whereas the pyruvate and PEP return to the mesophyll (Figure 2). In PCK plants,

PEP can be used directly by PEP carboxylase in the next round of the cycle. In NADP-ME and NAD-ME subtypes, pyruvate is converted to PEP by pyruvate, phosphate-dikinase (PPDK) in the M chloroplasts using the equivalent of two ATP molecules. The ATP expenditure by PPDK or PCK during PEP regeneration is considered to be the principle cost of operating the C₄ metabolic cycle.

Anatomical Modifications (Kranz Anatomy)

In most C₄ plants, the inner compartment where Rubisco is localized and CO₂ concentrated is a layer of cells that ring the vascular bundles in a leaf. This layer is commonly called the bundle sheath (BS) out of convenience. In many C₄ lineages, the BS is derived from anatomically correct BS cells, however, in numerous others the 'BS' is derived from mesophyll sheath and water storage cells. C₄ BS cells are typically enlarged relative to what occurs in the C₃ leaf, and are half-filled with numerous large chloroplasts (Figure 3). The M cells fill much of the volume of C₃ leaves such that there are typically many (5–20) M cells between adjacent veins (Figure 3(a)). In C₄ plants, by contrast, the M cells are typically reduced into one

or two concentric layers that ring the BS tissue. Together, the ring of tissue formed by BS and M cells create a wreath-like layer of cells around the vascular bundle termed Kranz anatomy.

Single-Cell C₄ Photosynthesis

In more than 99% of C₄ plants, the C₄ metabolic cycle functions between two distinct cell layers, typically the M and BS tissues. However, a dozen or so species have been identified where the C₄ pathway functions completely within a single cell. These are the single-cell C₄ species. Only three species of single-cell C₄ plants are known in the terrestrial flora, from two evolutionary lineages. In the monospecific *Sueada aralocaspica* lineage, CO₂ is pumped from the outer to the inner end of an elongated M cell (Figure 4(a) and 4(c)). In the two species of the *Bienertia* lineage, CO₂ is concentrated into a ball of chloroplasts in the middle of a large, succulent M cell (Figure 4(b) and 4(d)). The remaining single-celled species all occur in submersed, aquatic plants, either in the monocot family Hydrocharitaceae or in various lines of eukaryotic algae. Unlike terrestrial plants, where the C₄ pathway is

Figure 3 Transverse sections of C₃ and C₄ leaves, demonstrating five of the major anatomical patterns identified in leaves in C₄ plants. (a) The C₃ grass *Brachypodium distachyon*, a model C₃ grass. (b–f) C₄ plants of different evolutionary origins: (b) *Zea mays*, a classic NADP-ME-type grass; (c) *Muhlenbergia montana*, a classic NAD-ME grass; (d) *Atriplex rosea*, an Atriplicoid-type NAD-ME dicot from the Chenopodiaceae; (e) *Salsola kamarovii*, a salsoloid-type NADP-ME dicot from the Chenopodiaceae; (f) *Zygophyllum simplex*, a kochioid-type NAD-ME dicot. Arrows indicate bundle sheath chloroplasts where Rubisco is localized. *Abbreviations:* B, bundle sheath cell; M, mesophyll tissue, V, vascular tissue. The horizontal bars indicate 15 μm.

Figure 4 The two forms of leaf anatomy in terrestrial single-cell C₄ plants. (a, c) Leaf anatomy of *Suaeda aralocaspica* showing whole-leaf (panel a) and mesophyll cell (panel c) views. (b, d) Leaf anatomy of *Bienertia cycloptera* showing whole leaf (b) and mesophyll cell (d) views. For *S. aralocaspica*, P indicates the end of the cell where PEP is formed; R indicates where Rubisco is localized. Arrows indicate the movement of C₄ organic acids or the movement of pyruvate (C₃ acids) within the cells. In *S. aralocaspica*, PEP carboxylase forms C₄ acids at the outer (P) end of the cell, whereas decarboxylation occurs at the inner end of the cell (R). In *B. cycloptera*, C₄ acids are formed at the cell periphery, whereas decarboxylation occurs in the chloroplast ball in the middle of the cell. Other abbreviations: meso., mesophyll cells; VB, vascular bundles; WC, water storage tissue. Reprinted from Sage RF (2004) The evolution of C₄ photosynthesis. *New Phytologist* 161: 341–370, with permission from Wiley.

always expressed in aerial tissues, in aquatic C₄ organisms, the C₃ pathway predominates when CO₂ is abundant whereas the C₄ pathway is expressed when CO₂ is deficient. These species are thus considered to be facultative C₄ plants. In the aquatic plants and algae, CO₂ is concentrated into chloroplasts, but there is no distinct anatomical difference from the C₃ mode. For this reason, there has been some debate as to whether they should be termed C₄ species. Since there is CO₂ concentration into a compartment where Rubisco is localized (the chloroplast), a key criterion of C₄ photosynthesis is met and they are now generally considered to be C₄ plants. C₄ algae are generally not included in C₄ discussions, in part because few have been identified and the overall significance of C₄ photosynthesis in algae is poorly known. This review continues the practice of emphasizing C₄ photosynthesis in higher plants (=kingdom Plantae). For a review of C₄ algae, see Bowes (2011).

Diffusion Barriers Preventing CO₂ Loss

Compartmentalization of Rubisco and the decarboxylating enzymes in an inner compartment contributes to CO₂ concentration in two ways. First, the compartmentalization localizes Rubisco to the immediate vicinity of the decarboxylation reaction. Second, it serves to trap the CO₂ near Rubisco before it can escape back into the mesophyll and intercellular air spaces. This trapping ability requires the presence of a diffusion barrier to slow CO₂ efflux. In numerous grasses, the diffusion barrier is a thick BS wall impregnated with the waxy compound suberin. In other grasses and the dicot C₄ lineages, chloroplasts and the decarboxylating enzymes are located on the centripetal (inner) end of the BS cells, near the vascular tissue, and a large vacuole separates them from the outer edge of the BS cell. CO₂ diffuses 10,000 times slower through water than air, so a large vacuole can serve as an effective diffusion barrier.

In the terrestrial single-celled C₄ species, a large vacuole between the site of decarboxylation and the intercellular air space slows CO₂ efflux (Figure 4).

Physiological Significance

Photosynthetic Responses to Atmospheric CO₂ and Temperature

The C₄ pathway has two immediate benefits: first, it raises the CO₂ content in the BS to levels that enable Rubisco to operate close to its maximum activity. Second, the concentration of CO₂ around Rubisco greatly reduces photorespiration. For high rates of photorespiration, CO₂ levels in the atmosphere must be less than about 500 ppm (Figure 5(a)). Elevated levels of CO₂ (>1000 ppm) effectively inhibit the rate of RuBP oxygenation, whereas the current level of about 390 ppm allows for modest (20%) photorespiratory inhibition near 25 °C (Figure 5(a)). Atmospheric CO₂ levels have been sufficiently high through geological time to effectively suppress photorespiration, with two low CO₂ episodes occurring during the history of land plants (the past 400 million years). A low CO₂ episode is estimated to have occurred during the Carboniferous and Permian periods in Earth's history, centered around 300 mya (million years ago), and recently, in the past 35 million years (Figure 6(a)). During these periods, modeled activities of Rubisco oxygenation at 30 °C are predicted to have been significant, particularly in the past 500,000 years, when CO₂ levels were generally below 300 ppm (Figure 6(b)). At present, the level of atmospheric CO₂ is anthropogenically enhanced by one-third over the 260–280 ppm that persisted during the Holocene epoch of the past 10,000 years, and are about double the CO₂ levels that predominated in the late Pleistocene (10,000–50,000 years ago). As a result of these lower CO₂ levels in recent geological

Figure 6 The modeled change in atmospheric CO₂ content (a) and corresponding rates of Rubisco oxygenase activity relative to carboxylase activity over the past 500 million years. The oxygenation/carboxylation ratio was modeled at 30 °C assuming spinach-type of Rubisco and O₂ levels of 21%. Adapted from Sage RF (1999) *Why C₄ Plants?* In: Sage RF and Monson RK (eds.) *C₄ Plant Biology*, pp. 3–16. San Diego: Academic Press.

Figure 5 The relationship between photorespiratory inhibition of photosynthesis and chloroplast CO₂ content in C₃ plants at 21% atmospheric O₂. The brackets indicate the range of chloroplast CO₂ levels (C_c) that correspond to atmospheric CO₂ levels (C_a) of the current era (390 ppm), the preindustrial Holocene era (270 ppm), and the late Pleistocene epoch (~200 ppm). (b) The relationship between chloroplast CO₂ and carboxylation potential (V_c–0.5V₀) expressed relative to the maximum rate of Rubisco at CO₂ saturation.

time, photorespiration was much higher in C₃ plants than it is today, and this reduced the photosynthetic potential of C₃ relative to C₄ vegetation.

The third requirement for high rates of photorespiration is warm temperatures. At low temperatures (<15 °C), the rate of photorespiration is low because Rubisco has low specificity for O₂ relative to CO₂. As temperature increases, the specificity of Rubisco for O₂ increases relative to that for CO₂ and the solubility of CO₂ relative to O₂ declines. Together, these responses enhance RuBP oxygenation such that above 35 °C, photorespiration inhibits photosynthesis by more than 30% in current atmospheric conditions and by more than 40% at preindustrial CO₂ levels of 270 ppm (Figure 5(a)). By contrast, because of the high level of CO₂ in the BS, photorespiration in C₄ plants is marginal (<6% of the rate of photosynthesis) at all temperatures (Table 3). Temperature also affects the kinetics of Rubisco in a manner that has significance for C₄ photosynthesis (Figure 5(b)). At low temperature (<12 °C), Rubisco operates relatively close to CO₂ saturation in the current atmosphere. As temperatures rise, the amount of CO₂ required to saturate Rubisco increases, such in current atmospheric conditions above 30 °C, the enzyme in C₃ plants is operating well below its maximum rate. By raising CO₂ levels in the BS, C₄ plants are able to operate Rubisco near its maximum, substrate-saturated activity ($V_{\max}$) at all temperatures (Figure 5(b)).

Together, the ability to reduce photorespiration and operate Rubisco near CO₂ saturation confers substantial photosynthetic advantages for C₄ plants in warm climates and low-CO₂ atmospheres. These differences are well demonstrated by comparing the CO₂ and temperature responses of photosynthesis between C₃ and C₄ species of similar ecological habitat, for example, in prairie grasses or agricultural weeds (Figures 7 and 8). Comparisons of the CO₂ response show that C₄ species always have a CO₂ compensation point of photosynthesis (the minimum CO₂ requirement for

positive photosynthesis) near 0 ppm; by contrast, the CO₂ compensation point in C₃ plants is near 60 ppm at 31 °C (Figure 7(a)). C₄ plants have a steeper CO₂ response of net CO₂ assimilation rate at low CO₂ levels than C₃ species, which combined with the lower CO₂ compensation point, enables them to have a higher photosynthesis rate at low to current CO₂ values (Figure 7(b); Table 3). C₄ photosynthesis becomes CO₂ saturated at CO₂ levels near the current atmospheric value, whereas C₃ plants show substantial photosynthetic enhancement with CO₂ enrichment above the current atmospheric value. Thus, at elevated CO₂, C₃ species typically have similar or greater carbon assimilation rates than their C₄ competitors.

The temperature response of photosynthesis in C₃ plants at current CO₂ levels tends to be weaker than that of C₄ species. At current CO₂ levels, C₃ plants have a relatively broad thermal optimum in contrast to the narrow and higher thermal optimum of C₄ photosynthesis (Figure 8(a); Table 3). Typically, C₄ plants have substantially greater CO₂ assimilation rates at elevated temperatures (>30 °C) than C₃ plants of similar ecological habit whereas C₃ species often have higher rates below 20 °C. At double the current CO₂ level, C₃ plants retain their advantage at low CO₂, whereas they have similar photosynthetic capacities at elevated temperature as C₄ species (Figure 8(b)). This enhancement of net CO₂ assimilation rate in C₃ species by rising CO₂ is due in large part to the suppression of the high rates of photorespiration that inhibit carbon gain at current levels of CO₂ in C₃ plants. C₄ plants lack this inhibition and so are relatively unresponsive to increasing CO₂ levels above current values (Figure 8).

In warm environments, these differences translate into significant photosynthetic and growth advantages for C₄ species in the atmospheric conditions of the past 20,000 years. In crops and weeds, for example, C₄ species in a warm climate typically have greater photosynthetic capacity, higher daily

Table 3 Characteristics of C₃ and C₄ crops and weeds for atmospheric conditions of the late twentieth century^a

Attribute	C ₃	C ₄	Units
Maximum photosynthesis rate	20–50	35–75	μmol m ⁻² s ⁻¹
Maximum daily production rate	10–40	40–80	g m ⁻² d ⁻¹
Maximum biomass yield	1–5	3–8	kg DM m ⁻² year ⁻¹
Photosynthetic thermal optimum	15–30	30–40	°C
Photorespiration/photosynthesis @ 10 °C	8%	1–6%	
@25 °C	25%	1–6%	
@40 °C	40%	1–6%	
δ ¹³ C	–20 to –35	–10 to –15	‰ (per mil)
Intercellular CO ₂	200–300	100–200	ppm

production rates, and yield more biomass during a growing season than do C₃ species (Table 3). As a comparison, the world record crop production in terms of dry biomass is close to 100 t per hectare by numerous tropical C₄ grasses; the world record yield from a C₃ crop is near 50 t per hectare.

The advantages of the C₄ pathway do not come without costs. In C₃ plants without photorespiration, assimilating each CO₂ costs 2 NADPH and 3 ATP to fix it into carbohydrate end products. In C₄ plants, 2 NADPH and 4.7 ATP (in PCK subtypes) or 5.7 ATP (in NADP-ME and NAD-ME subtypes) are needed, assuming that 25% of the pumped CO₂ leaks out of the BS (Table 4). The higher ATP cost of C₄ photosynthesis reflects the energy required to pump CO₂ into the BS. As the rate of photorespiration increases in C₃ plants, the energy costs of photosynthesis rise, such that they are equivalent to

that of C₄ plants at 25–30 °C, and greater above about 30 °C. Differences in the energy requirement of photosynthesis are demonstrated by comparing differences in the light-use efficiency (quantum yield) of C₃ and C₄ plants as a function of temperature (Table 4; Figure 9). C₃ species at current CO₂ levels have superior quantum yields at cool temperatures, but lower quantum yield than C₄ species at warm temperature. Using quantum yields, it is possible to model the relative performance of C₃ versus C₄ photosynthesis as a function of CO₂ and temperature (Figures 9 and 10). As temperature increases, the CO₂ concentration required to favor C₃ over C₄ plants increases as well. Whereas C₃ grasses outperform C₄ grasses below 200 ppm below 15 °C, at 35 °C they need at least 500–600 ppm to show superior performance (Figure 10).

Table 4 Energy requirements for carbon metabolism to triose phosphate, and associated quantum yields of C₃ and C₄ plants at 30 °C^a

	ATP	NADPH	Quantum yield at 30 °C, 350 ppm CO ₂
<i>C₃ photosynthesis</i>			
No photorespiration	3	2	0.078
With 32% photorespiration	5	3.2	0.053
<i>C₄ photosynthesis</i>			
NADP-ME and NAD-ME types			
C ₃ cycle	3	2	
C ₄ cycle	2	—	
25% leak rate	0.5	—	
3% photorespiration	0.15	0.1	
Total	5.65	2.1	0.055–0.068

Enhancement of Water- and Nitrogen-Use Efficiency

Because the C₄ cycle has a high capacity to concentrate CO₂ into the BS, even at low atmospheric CO₂ levels, C₄ plants will have less open stomata than C₃ species with the same photosynthetic rate. This reduces the rate of transpiration in C₄ relative to C₃ plants and leads to significant enhancement in water-use efficiency (WUE). Typically, C₄ species have two to three times the WUE of ecologically similar C₃ species (Table 3). Even at very low stomatal apertures that would yield negligible rates of CO₂ assimilation in C₃ plants, C₄ plants are able to have significant rates of photosynthesis. This is most important in hot, arid regions, where evaporative demands are so high that anything but low stomatal apertures could lead to unsustainable rates of water loss. High WUE also assists C₄ species in saline soils, apparently by reducing the volume of transpiration water from which salt must be filtered. In addition to improved WUE, C₄ plants have higher nitrogen-use efficiencies (NUEs) of photosynthesis, typically 1.5–3 times that of C₃ species (Table 3). Because C₄ plants operate Rubisco near CO₂ saturation and greatly reduce oxygenase activity, they require about 25% as much Rubisco as C₃ species of equal photosynthetic capacity, and have very low levels of photorespiratory enzymes. As a consequence, C₄ plants have

Figure 9 The modeled response of the maximum photosynthetic quantum yield (=light use efficiency) from C₃ plants at atmospheric CO₂ levels equivalent to the last glacial maximum (180 ppm), current (350 ppm, in 1990), and late in this century (500 ppm). The range of quantum yield measured in a variety of C₄ plants is shown for comparison as a gray band. CO₂ variation has little effect on maximum C₄ quantum yield. Adapted from Ehleringer JR, Cerling TE, and Helliker BR (1997) C₄ photosynthesis, atmospheric CO₂, and climate. *Oecologia* 112: 285–299, with permission from Springer.

Figure 10 The effect of daytime growth season temperature on the atmospheric CO₂ concentration at which performance of C₃ species equals that of C₄ species. Crossover temperatures were determined as the CO₂ levels needed for equivalent maximum quantum yields at a given temperature. C₄ photosynthetic performance is superior in the black regions of the figure; C₃ photosynthetic performance is superior in the gray region of the figure. Adapted from Ehleringer JR, Cerling TE, and Helliker BR (1997) C₄ photosynthesis, atmospheric CO₂, and climate. *Oecologia* 112: 285–299, with permission from Springer.

about 30% less nitrogen per unit leaf area than ecologically similar C₃ species. Higher NUE promotes superior performance of C₄ grasses in nitrogen-deficient soils, such as those of tropical grasslands. The reduced leaf N arising from higher NUE also reduces the nutritional quality of C₄ leaves, which can have major consequences for grazing herbivores.

C₄ Biogeography

The distinct physiology of C₄ photosynthesis plays a major role in determining where C₄ plants are able to occur and dominate C₃ plants. As a result of their superior photosynthetic performance at high but not cool temperatures, C₄ species can dominate warm environments, but are uncommon in cool environments. They are also uncommon in shaded environments, due in part to their inferior quantum yields below 25 °C. The primary requirements for the success of C₄ plants are therefore warmer temperatures and access to at least moderate light intensities. Aridity, soil nitrogen supply, and salinity also affect the success of C₄ plants, but these are secondary in that they are primarily significant in warm, illuminated habitats but are inconsequential in cold or shaded environments.

Primary Controls: Temperature and Light

The critical temperature parameter affecting C₄ plant distribution is growth season temperature. In the temperate zones, C₄ plants tolerate severe cold outside of the growth season as well as co-occurring C₃ species, and often tolerate low night temperature as well as their C₃ associates. During the growing season, however, daytime leaf temperature must routinely rise above 25 °C for C₄ plants to be present in a community. Where daily temperatures commonly rise above 30 °C during the growing season, C₄ plants generally dominate grass and sedge floras of open landscapes. When plotted on the basis of growth season temperature (which reflects night and morning temperatures as well as the afternoon high), C₄ plants dominate grassland floras and biomass above 20–22 °C. Above growth season averages of 23–24 °C, C₃ grass productivity in open grasslands is very low (typically less than 10% of total biomass). At the other end of the spectrum, C₄ biomass is rare to absent where the temperatures at the peak of the growing season average less than 12–14 °C. Some C₄ species occur in cold climates, but these are restricted to warm microsites where daytime temperatures rise above the regional average. For example, a few dozen C₄ species grow in alpine regions of the world up to 5200 m. These species exploit high solar irradiance in the alpine zone to warm the leaf canopy to >25 °C on sunny days, but they must also tolerate low, often subzero, growth temperatures during cloudy days and at night. These examples demonstrate that cold *per se* does not exclude C₄ species, rather the lack of warm daytime temperatures prevents C₄ plants from ecological success.

The influence of temperature over the distribution of C₄ plants is demonstrated by altitude and latitude transects that examined the proportional contribution of C₄ grasses to regional grass floras. In regions where C₄ grasses dominate lowland grass floras, their representation in the grass flora

declines as elevation increases, such that they are uncommon above 2000–3000 m. Along latitude transects, the transition between C₃- and C₄-dominated floras corresponds to temperate latitudes, as is demonstrated by a survey of grass floras of the world's oceanic islands (Figure 11). Above >50° latitude, C₄ species are rare or absent, whereas below temperate latitudes (<30°), C₄ grasses dominate the grass flora of any given island. On larger tropical islands, where extensive forests form, a significant number of C₃ forest grasses are present, so that the C₄ contribution may only be 70% of the grass flora. On smaller islands and atolls, where soils tend to be shallow, sandy, and drought-prone, the grasses are often all C₄.

The second requirement for C₄ success is availability of moderate to high light intensity. Typically, this means that C₄ species require 30–50% of full sunlight intensities if they are to dominate a local habitat. In forest canopies where light intensities average less than 20% of full sun on a clear day, C₄ species rarely occur, regardless of latitude. The failure of C₄ plants to dominate in low-light environments results from a combination of factors. Shaded environments tend to be cool (<30 °C at midday), so that high temperatures favoring C₄ species are not frequently encountered. In shade, much of the carbon a plant acquires is obtained from sunflecks (brief episodes of high light). C₄ species are less able to exploit short sunflecks than C₃ species. Also, because shaded environments tend to be cooler and more humid, C₃ plants often have more open stomates than they otherwise would. This allows for higher intercellular CO₂ levels in shade plants, thereby promoting greater photosynthetic efficiency.

The failure of C₄ species to do well in shaded settings has important consequences for the distribution of C₄-dominated life-forms and biomes around the globe (Tables 5 and 6). Establishment in woodlands generally requires some level of shade tolerance; if C₄ species do poorly in shade, then it would be difficult for them to establish under the canopy of a forest. This reasoning explains why there are no canopy-forming trees or vines using the C₄ pathway, with the

Figure 11 The percentage representation of C₄ grasses in the grass flora of the oceanic islands of the world. The upper oval encloses islands from the western Atlantic/Pacific regions where summers are wet. The lower oval encloses islands from the eastern Atlantic/Pacific where summers are dry. Table 5 Principal life-forms of C₄ plants^a

Life-form	C ₄ families	Examples
Trees	None	
Sub-trees (5–10) ^b	Chenopodiaceae	<i>Haloxylon</i> spp. (xerophytic halophytes and psammophytes ^c)
	Polygonaceae	<i>Calligonum</i> spp. (xerophytic psammophytes)
	Euphorbiaceae	<i>Euphorbia</i> (= <i>Chamaesyce</i>), (three small Hawaiian trees)
Vines	None	
Shrubs (500)	Amaranthaceae	<i>Aerva</i> , <i>Gomphrena</i>
	Chenopodiaceae	<i>Anabasis</i> , <i>Atriplex</i> , <i>Haloxylon</i> , <i>Salsola</i> , <i>Suaeda</i> (mostly xerophytic halophytes and psammophytes)
	Euphorbiaceae	<i>Euphorbia</i> spp. (= <i>Chamaesyce</i>)
	Polygonaceae	<i>Calligonum</i> spp. (xerophytic psammophytes)
Forbs (dicot herbs) (1200)	All dicot C ₄ families	Summer desert annuals, xerophytic annual and perennial herbs of low latitudes, tropical and summer-active weeds, psammophytic herbs of low latitudes, tropical beach herbs
Graminoids (5800)	Poaceae	Grasses, mainly of low-latitude and warm temperate summer habitats
	Cyperaceae	Sedges, mainly low-latitude and warm temperate wetlands

^aSub-trees refer to species that develop arborescence with age, but never rise above 12 m in height.

^bNumbers in parenthesis refer to the estimated number of species in each life-form.

^cPsammophytes are plants of sandy soils.

Table 6 Major biomes of the World with high C₄ plant representation (loosely defined as > 25% of the vegetative cover) or low (< 1%) C₄ representation^a

Biome	Major location
<i>High C₄ representation</i>	
Tropical, subtropical grassland, and savanna	South and Central America, Africa, India, S.E. Asia, Australia
Warm temperate grassland and savanna	Central and S.E. North America, N. Argentina, Australia
Arid steppe (low to middle latitudes)	S.W. North America, central Asia, Australia, Africa
Beach dunes and bluffs, warm temperate to tropics	Global
Tropical, subtropical wetlands (nonarborescent)	Global, especially South America, central Africa, S.E. Asia
Salt marsh (warm temperate to tropical)	Global, but more temperate owing to mangrove dominance in tropics
Salt desert (< 45° latitude)	W. North America, central Asia, central Australia
Hot deserts and semideserts	Southwest North America, Africa, Australia, S.E. Asia
Disturbed ground (low latitudes, low altitude)	Global
<i>Always C₃ dominated (low C₄ representation)</i>	
Forests	Global
Tundra	Polar latitudes, high mountains (all latitudes)
Heathlands	N. Europe, Canada, Russia
Cool temperate grasslands and savanna	Canada, N.W. U.S.A., S.E. Europe, S. Russia, Australia, S. Argentina, Tasmania
Montane grasslands	Global, elevations between 2000 and 4000 m
Mediterranean grasslands	California, Chile, S. Europe, Asia Minor, N. Africa, S. Africa, S.W. Australia
Mediterranean-type shrublands (chaparral and matorral)	California, Chile, S. Europe, Asia Minor, N. Africa, S. Africa, S.W. Australia
Temperate to boreal wetlands, Tiaga	Canada, N. Europe, Russia, New Zealand, Patagonia
Cold deserts and semideserts	W. North America, N. central Asia, Tibet
Salt marshes (> 50° latitude)	Global
Mangles (mangrove swamps)	Tropical, subtropical latitudes
Disturbed ground (high latitude and altitude)	Global

exception of a few desert shrubs that become arborescent with advanced age, and a few rare species of small trees from Hawaii (Table 5). Some C₄ grasses have evolved shade tolerance in warm climates and are found in forest understories;

however, these are not dominant and do not occur in the dense shade of old-growth canopies. Thus, in warm to hot climates, the absence of forest and woodland is the single greatest indicator of C₄ abundance and diversity. Where forests

are present, the light environment will typically be too low to support more than a few C₄ species. Where forests are absent, either because of edaphic factors (shallow, nutrient-poor or saline soils), severe abiotic stress (killing drought), mechanical stress (wind, waves, or flooding), or severe disturbance (logging, fire, large animal activity), C₄ plants will be important components of the regional diversity. C₄-rich habitats include beaches along warm temperate to tropical coasts where wave action prevents woody dominance, tropical swamps, and floodplains where flooding prevents dominance by a woody plant canopy, abandoned cropland at low latitudes, salty soils, and warm temperate to tropical grasslands (Table 6). For example, in sub-Saharan Africa, the margins of lakes and slow-moving rivers are dominated by papyrus (*Cyperus papyrus*), a C₄ sedge. Here, floodwaters exclude the forest trees. In the African savannas, elephants, giraffes, and fire aid in the reduction of C₃ *Acacia* trees that otherwise would dominate the landscape. Where elephants and fire become common, wooded landscapes are converted to C₄ grassland. Fire control and excessive poaching of elephants permit woodland formation, leading to a loss of the C₄-dominated grasslands.

Secondary Controls: Moisture, Nutrients, and Salinity

Moisture Availability

Aridity is often noted to directly favor C₄ over C₃ biomass, because the higher WUE of C₄ species theoretically promotes their competitiveness in arid situations. In addition, interactions between aridity and other ecological factors, notably fire, are critically important. In the case of fire, aridity slows growth of woody species, thereby increasing their establishment time and the period during which they are vulnerable to fire injury. Aridity also enhances the probability of initial fire establishment, its subsequent rate of spread, and its intensity. In contrast to most woody species, C₄ grasses are typically fire tolerant, as their meristems are protected below ground or in fire-resistant tufts. Forest plants, by contrast, are intolerant of fire. Thus, the success of C₄ grasses in semiarid regions is typically promoted by fire because it reduces the woody competition.

The WUE advantage of C₄ photosynthesis is perhaps most critical in dry locations, such as hot deserts in Africa, Asia, and northern Australia, and semiarid grasslands of low-to-mid latitudes. Here, lack of rainfall combined with high daily temperature creates conditions where the transpiration potential may be greater than what a C₃ plant could support, particularly in the seedling stage. C₄ species not only survive, but they can also thrive under thermal regimes that are harmful to most C₃ species. Consequently, C₄ plants are common if not dominant in the hot arid zones of the Earth. By contrast, the floras of deserts at high latitude or high elevation are exclusively C₃, reflecting the generally poor ability of C₄ species to compete in cold climates, regardless of any aridity that may be present.

Seasonality of precipitation has great importance for the success of C₄ vegetation in mid-latitudes. Temperate grasslands can be almost completely C₃ or C₄ depending on the timing of precipitation. Grasslands of Mediterranean climate zones (southern Europe, North Africa, California, Chile, southwestern Australia, and southwestern Africa) have

abundant winter precipitation but lack summer precipitation. The winters are cool and moist, allowing for lush growth of C₃ plants, whereas summers are so dry that plant growth is not possible except near watercourses. If summer precipitation does occur (even a small amount), then plants can be active and many of these are C₄ species. Hence, at similar latitudes, temperate monsoon grasslands with significant summer precipitation are dominated by C₄ grasses, whereas grasslands from Mediterranean-climate zones are dominated by C₃ grasses that are dormant in the summer. For example, the southwest tip of Africa near Capetown has a Mediterranean-type climate and <10% C₄ species in the grass flora. At Durban, on the eastern coast of South Africa at similar latitudes, the bulk of the precipitation falls during the warm season and the grass flora is 75% C₄. In California, nearly all the precipitation falls in the cool months, and the native grass flora of the valley grasslands is almost completely C₃; by contrast, along the Gulf coast of Texas, in Florida, and the US Atlantic coast of Georgia at similar latitudes, there is an abundance of summer precipitation and the grasslands are C₄ dominated. Oceanic islands show a similar pattern. In the eastern Atlantic and Pacific at temperate latitudes, summer rain is rare and C₄ presence is low (Figure 11). On the western edges of these oceans, summer precipitation is abundant as are C₄ grasses.

In southwestern North America, the Mojave desert in California receives 60–90% of its precipitation during the winter, and as a consequence has a high proportion (40%) of C₃ grasses in the grass flora. The Chihuahuan desert in southwestern Texas receives the majority of its precipitation in summer, and C₃ grasses are infrequent (20% of the grass flora). Due in part to the low summer precipitation, the Mojave Desert lacks native grasslands, in contrast to the Chihuahuan desert, where C₄ species dominate the desert grass flora. In addition, two floristic seasons are often present in warm temperate deserts. In the deserts of the American Southwest, winter rains and mild temperatures support a rich flora of C₃ annuals that produce spectacular blooms during wet years. By contrast, summer rains produce a rich flora of C₄ annuals (Table 7). Because C₄ annuals typically produce inconspicuous flowers, the blooms of summer annuals fail to attract the attention of tourists that the cool-season C₃ blooms receive.

Salinity

Moderate salinity also favors C₄ species, apparently because the inherently greater WUE reduces the salt load that the plants must deal with in the transpiration stream. In temperate to tropical latitudes, soils of moderate salinity are commonly dominated by C₄ species (Table 6). For example, C₄ shrub species in *Atriplex* (saltbush; Chenopodiaceae) can form dense brush on saline soils of central Asia, the Americas, and Australia. In coastal estuaries, salinity establishes a paradoxical trend where low-latitude estuaries are dominated by C₃ species whereas temperate estuaries are dominated by C₄ marsh grasses. In low-latitude estuaries, C₄ grasses can be abundant following a major disturbance; in time, C₃ mangrove trees invade and eventually form dense forests that dominate the estuaries. Mangroves are unique in the plant kingdom in that they are the only tree species that can tolerate both flooding and high salinity. They are, however, freezing intolerant and are excluded from the temperate zone by periodic winter

Table 7 Photosynthetic pathway and mean density over a 10-year period for the 12 most abundant species of summer and winter annuals on the Cave Creek Bajada, near Portal, Arizona (Chihuahuan Desert)

Species	Photosynthetic pathway	Density (plants per 0.25 m ⁻²)
<i>Winter annuals</i>

frosts. The resulting lack of mangrove competition allows C₄ grasses to dominate estuary communities in the temperate zone, where they form highly productive saltmarshes. C₄ saltmarshes in the temperate zone typically have low plant diversity because one or two species in the C₄ grass genus *Spartina* effectively exclude most C₃ plants.

Moderate salinity also allows C₄ species to dominate landscapes in climate zones that may otherwise be too cold. *Spartina* marshes predominate in cool-temperate eastern Canada and northern Europe at latitudes where inland there are few if any C₄ species. Along the cool-temperate coastline of northern California, C₄ salt grasses (*Distichlis* spp.) can dominate coastal bluffs, marshes, and cliff ledges because higher salinity allows them to compete with the local C₃ flora for much of the year. Away from the coastline, there are few native C₄ species.

The Evolution of C₄ Photosynthesis

Polyphyletic Origins

Taxonomic Diversity

In the plant kingdom, there are an estimated 7500 C₄ plant species in 10 taxonomic orders and 19 families (Table 8). All terrestrial C₄ species are angiosperms, and all occur in the

more advanced angiosperm families of the monocots and eudicots. No ferns, gymnosperms, or lower vascular plants are known to employ C₄ photosynthesis. In proportional terms, <3% of the world's terrestrial flora is C₄; however, this relatively low value in terms of floristic composition is offset by the high productivity and ecological success of many C₄ species across the planet. In terms of net primary productivity (NPP) of land plants, C₄ plants contribute about a fourth of the global terrestrial NPP, far higher than their limited numbers would indicate.

The distribution of C₄ photosynthesis within the angiosperm phylogeny is dispersed, although most C₄ families are clumped in two orders, the Poales and Caryophyllales (Figure 12). Most C₄ species are monocots, with half being grasses (Poaceae, with about 400 genera and 4500 C₄ species), and half of the remaining species being sedges (Cyperaceae, with 17 genera and 1300 species) (Table 8). Eudicots account for about a quarter of the world's C₄ flora. In the eudicots, most C₄ species occur in the Chenopodiaceae (550 C₄ species), Amaranthaceae (250 species), and Euphorbiaceae (250 species).

Evolutionary Lineages

Extensive phylogenetic analysis demonstrates that C₄ photosynthesis is one of the most convergent of complex evolutionary phenomena in the living world. There are currently an estimated 66 distinct evolutionary lineages of C₄ photosynthesis (Table 8). The single most prolific family in terms of C₄ origins is the grass family, with 22 distinct origins of the C₄ pathway, followed by the Chenopodiaceae with 10 estimated origins. Sedges evolved the C₄ pathway six times, whereas there are five origins in the Amaranthaceae. Multiple origins are also observed in the Asteraceae (four C₄ lineages), Cleomeaceae (three C₄ origins), and Nyctaginaceae (two C₄ origins). Numerous genera also have evolved the C₄ pathway on multiple occasions. *Suaeda* (Chenopodiaceae) has four distinct lineages, including the two single-celled C₄ lineages found in land plants; *Cleome* (Cleomeaceae) has three C₄ lineages, whereas *Eleocharis* (Cyperaceae), *Mollugo* (Molluginaceae), and *Flaveria* (Asteraceae) have two each. A prolific ability to evolve C₄ is not correlated with species numbers. *Euphorbia* has evolved C₄ photosynthesis just once and has more than 200 C₄ species; whereas *Cleome* has only one C₄ species in each of its three lineages.

With the identification of the many C₄ lineages, it is now possible to delineate the geographic regions where the C₄ pathway evolved by identifying the distributions of the species that branch at nodes between full C₃ and C₄ species on a phylogeny. Centers of origins occur on all low-to-mid latitude continents, largely in semiarid to arid regions having hot summers that receive episodic precipitation from monsoon rains (Figure 13). The most prolific centers of origin occur in central Asia, where *Calligonum* (Polygonaceae) and all 10 of the Chenopodiaceae lineages arose, and southwestern North America and adjacent Mexico, where at least eight lineages arose.

When Did C₄ Plants Evolve?

Molecular clock analysis of phylogenetic data also indicates when the C₄ pathway arose. The oldest C₄ lineage estimated

Table 8 The occurrence of C₄ photosynthesis in higher plant orders and families

by molecular clock methods is the grass subfamily Chloridoideae, which is approximately 30–35 million years old (Figure 14(a)). The oldest estimated eudicot lineage is the Chenopodiaceae subfamily Caryoxylonae, estimated to have arisen about 25 mya. The remaining C₄ lineages evolved over the subsequent 25 million years, with a greater number arising 20–25 mya, and during the past 10 million years. The youngest lineages are estimated to have arisen in the genera *Neurachne* (Poaceae), *Eleocharis* (Cyperaceae), and *Flaveria* (Asteraceae) in just the past 2–3 million years, indicating that C₄ evolution may still be an on-going process. *Neurachne* and *Flaveria* contain species that have intermediate characteristics between C₃ and C₄ photosynthesis and thus have become important groups for studying the dynamics of C₄ evolution.

Why Did C₄ Photosynthesis Evolve?

The leading hypothesis explaining why C₄ photosynthesis evolved is the carbon starvation hypothesis, which proposes the C₄ pathway originated in response to reductions in photosynthetic potential associated with high rates of photorespiration and low availability of CO₂. A number of lines of evidence support this hypothesis. First, all the postulated

lineages of C₄ photosynthesis arose in the past 30–35 million years, after atmospheric CO₂ is estimated to have declined from levels where photorespiration is nil to levels where it would have been a significant inhibition on C₃ plants in hot climates (Figures 6 and 14(b)). CO₂ levels are estimated by geochemical models and proxy measurements to have been high (above 1000 ppm) between 40 and 100 mya, but declined to near current levels between 40 and 25 mya (Figure 6). Accompanying this CO₂ decline was a general drying of the planet, which expanded open, dry landscapes at low latitudes by the early Miocene. Second, the postulated centers of origin for the C₄ lineages correspond to regions where growing conditions were hot and episodically dry or saline (Figure 13). Examination of the closest C₃ relatives of C₄ lineages, and of C₃–C₄ intermediate species, consistently indicates that C₄ photosynthesis arose in summer active species that exploited episodic monsoon precipitation or salinized water supplies. Drought or elevated salinity are common in the habitats of these species, and evaporative demand is high due to the hot, generally dry climate. The presence of episodic summer moisture is significant because it allows for growth and photosynthesis during the hottest times of the year. If there were no summer moisture, the vegetation would be dormant, as occurs during the dry seasons at low latitude.

Figure 12 The distribution of C₄ evolutionary lineages in the angiosperm phylogeny. C₄ lineages are indicated in black branches, C₃ lineages by gray branches. The angiosperm phylogeny was generated from 9412 species, including C₄ species from 47 of the estimated 66 lineages. Numbers beside lineages indicate the number of distinct C₄ origins in the lineage. Drought stress, salt stress, and high evaporative demand reduce stomata aperture and lower intercellular CO₂ level in the leaf. This, in combination with low atmospheric CO₂ and high temperature (>35 °C), would keep CO₂ levels in C₃ chloroplasts low, thus promoting very high rates of photorespiration (>50% of the rate of photosynthesis) in atmospheres below 250 ppm CO₂. Such high levels of photorespiration would have inhibited the competitive ability and survival of C₃ plants, thereby opening up landscapes in extreme habitats where evolutionary experiments in carbon scavenging could proceed with minimal competition from C₃

vegetation. More importantly, however, high levels of photorespiration created a resource, photorespired CO₂, that could be exploited to offset the costs of photorespiration. Evolutionary selection for mechanisms to recapture photorespired CO₂ is now thought to have initiated the C₄ evolutionary process.

C₃–C₄ intermediate species from numerous evolutionary lineages demonstrate that C₄ photosynthesis arose from a series of innovations that initially served to capture and refix photorespired CO₂. Key early steps in the evolution of C₄ photosynthesis are the restriction of glycine decarboxylase to

Figure 14 (a) The age of 56 lineages of C₄ photosynthesis estimated from molecular phylogenetic data. The dot in each bar represents the median estimate for a lineage whereas the bars show the estimate ages of the stem and crown nodes in the phylogeny. Names indicate the lineage name as listed in Sage *et al.* (2011). (b) The change in atmospheric CO₂ concentration (black line) and oxygen isotope ratios in foraminifera sediments (gray line) since the early Eocene epoch. The corresponding appearance of C₄ fossil and isotope evidence is shown indicating the presence (dotted line) or rise to dominance (green triangle) of C₄ vegetation at low to mid-latitudes. Larger oxygen isotope ratios indicate a colder (high latitude) and drier (low latitude) planet. Abbreviations: Plio, Pliocene; PI, Pleistocene. the BS cells and increase in the number of BS chloroplasts. Glycine decarboxylase is the enzyme that releases CO₂ during photorespiration. These changes localize the release of photorespired CO₂ to the BS of C₃–C₄ intermediates, allowing Rubisco in the BS chloroplasts to refix it with high efficiency. The C₄ metabolic cycle is then upregulated to capture photorespired CO₂ leaking out of the BS cells, and full C₄ photosynthesis evolves when M expression of Rubisco and the PCR cycle is curtailed. When the evolutionary sequence indicated by the C₃–C₄ intermediate species is considered, the C₄ pathway is most directly an adaptation to high rates of photorespiration, rather than to high temperature, drought, or salinity. These environmental factors play a contributing role by promoting high rates of photorespiration, but are not directly the reason for C₄ photosynthesis. Habitats where these factors act in concert would have been the most likely to have produced C₄ plants, and consistently, most of the C₄ lineages originate in extreme environments where these factors occur in combination.

Rise to Ecological Dominance

While molecular clock evidence indicates when C₄ lineages began and taxonomically diversified, they do not address when C₄ plants became important elements in ecological communities. This information has to come from either fossilized tissues of identifiable C₄ plants, or the carbon isotope signatures derived from remains of C₄ plants or their herbivores. C₄ photosynthesis discriminates less against heavy isotopes of carbon (¹³C–CO₂) than does C₃ photosynthesis, such that C₄ tissues have eight to 15 more ¹³C atoms per hundred thousand ¹²C atoms than do C₃ plants. Using mass spectrometry, these differences can be readily detected in plant remains, or any material that originated from photosynthetic carbon. Thus, fossilized organic matter, soil carbonates, and animal remains can be assessed to determine whether C₃ or C₄ species were common to dominant on a landscape at the time of fossilization.

Fossilized soil carbonates and grass phytoliths (silica bodies) with C₄-like carbon-isotope ratios appear in Africa and the Americas between 16 and 23 mya, indicating C₄ plants become locally common (but not dominant) in open habitats by the Mid-Miocene epoch. The oldest known C₄ leaf fossils come from the Ricardo formation of southern California, dated from the middle Miocene at approximately 12.5 mya. These fossils show distinct C₄ Kranz-type leaf anatomy and have isotopic ratios indicative of C₄ species. Probable C₄ leaf fossils have also been found in the Fort Ternan formation of Kenya, dated at 14.5 mya.

While C₄ grasses become common by the mid-Miocene, there is no evidence that they dominate landscapes until after 10 mya. Beginning about 10 mya, C₄-dominated grasslands expanded across East Africa, southern Asia, and the interior of both North and South America. Both soil and herbivore remains from these areas show an increase in carbon isotopic ratios from C₃-like to C₄-like values between 10 and 5 mya. In East Africa and Pakistan, isotopic shifts are dramatic, indicating near-complete replacement of C₃ with C₄ vegetation in as little as 2 million years. In temperate latitudes

(China, South America, and the North American Great Plains), the increase in the carbon isotope ratio is less on average, indicating partial replacement of C₃ vegetation by C₄ species.

The expansion of C₄-dominated grasslands 5–10 mya appears to have resulted from climate change events that caused an increase in the seasonality of precipitation and overall aridity, such that summer monsoons would have alternated with pronounced dry seasons. There is little evidence for a significant drop in atmospheric CO₂ when the C₄ grasslands expand, so declines in CO₂ are not thought to be important drivers. Atmospheric CO₂ was already low in the late Miocene, however, so it could have been an important contributing factor that allowed other environmental agents such as increased seasonality to trigger C₄ grassland expansion. Increased aridity and seasonality of precipitation for grassland expansion would also have promoted wildfire, which would have favored fire-tolerant C₄ grasses over woody C₃ vegetation. Relatively high productivity of C₄ grasses would have produced an abundance of fuel to support frequent, killing fires during the dry season, whereas low CO₂ would have slowed establishment and succession of the woody vegetation. Consistently, late-Miocene deposits show increased soot and charcoal during the time when C₄-grasslands expanded.

Consequences of C₄ Plant Evolution for Animal Diversity

The evolution of C₄ photosynthesis produced a new plant functional type that could exploit opportunities created by low atmospheric CO₂ and more frequent drought. In a direct sense, this led to the diversification of 7500 new species, which is not much when compared to the estimated 250,000 C₃ species on the planet. As the novel C₄ species expanded across low-to-mid latitudes, however, they created novel conditions that triggered an evolutionary cascade, which in time led to the functional and trophic diversity in the grasslands biomes of the modern biosphere. Amongst the most significant changes was the expansion of open, low stature vegetation where sustained running was possible yet there was limited access to shelter. These open spaces would have favored novel traits in animals, such as herding in large numbers for defense against predators, extended strides for rapid locomotion, and dental structures adapted to grass. In response to the intensification of fire cycles promoted by C₄ grasses, fire-tolerant species evolved with traits such as below-ground storage organs and thick, heat-resistant bark. High productivity by the C₄ grasses also created an abundant food supply for grazing herbivores; however, much of the C₄ leaf protein is sequestered in BS tissues that are difficult to digest due to the thick BS wall. In response to this digestive challenge, megaherbivores with specialized digestive physiologies and extensive fermentation evolved to extract sufficient energy and protein from the C₄ forage. Among the megaherbivores that exploited the C₄ grasslands were the ruminant ungulates and the equines, whose large herds were maintained by the productive C₄ grasslands. The diversification of megaherbivores produced a vast resource of meat, which in turn promoted the evolutionary diversification of megacarnivores

such as the large cats. The rise of our own species may also be a response to the expansion of C₄ grasslands. C₄ grasses would have provided little for hominids to directly consume, because C₄ leaves are difficult to digest and the seeds are small and easily dispersed. Grazing herbivores, by contrast, would have been a valuable resource if hominids could have survived on the grassland and developed the ability to hunt or trap them. Expansion of C₄ grasslands in the late Tertiary period between 10 and 3 mya is thus hypothesized to have created an open habitat that selected for upright stature, teamwork, the use of weapons, and improved communication skills, which then led to increased brain size and cognitive ability. It is possible, therefore, that the rise of C₄ grassland formed the nursery for the evolution of rationale intelligence.

Global Change and the Future of C₄ Photosynthesis

Climate Change and Atmospheric CO₂ Enrichment

If C₄ plants evolved in response to past reductions in CO₂, then it follows that future increases in atmospheric CO₂ due to human activities would reduce the advantage of C₄ photosynthesis. Photosynthesis and growth of C₃ plants is enhanced 19–46% by a doubling in atmospheric CO₂; in C₄ plants, the stimulation is typically less than 10% if it occurs at all. As atmospheric CO₂ levels increase, cooler, more temperate environments would be affected initially, whereas C₄ species in warm, arid habitats would lose their advantage as atmospheric CO₂ levels increase 30–50% above the current value (Figure 10). There are, however, a number of considerations that indicate many C₄ plants will survive and continue to prosper in a world with higher CO₂.

First, rising CO₂ does not harm C₄ plants but does provide some benefits. Direct photosynthetic enhancement of C₄ photosynthesis by rising CO₂ is minor except during drought stress. The more significant impact of rising CO₂ on C₄ plants is that it reduces stomatal aperture, which lowers transpiration, improves WUE and delays the onset of drought. The degree of stomatal closure is similar in C₃ and C₄ plants, such that in systems where water is limited by high evapotranspiration and drought, similar responses of C₃ and C₄ species may be expected. However, water limitations are more likely in summer and semiarid landscapes where C₄ species currently dominate, so the impact of elevated CO₂ on drought could be more significant when and where C₄ plants are active. Because of this, C₄ plants could benefit as much from rising CO₂ as C₃ species in cooler environments.

Second, climate warming alone will generally favor C₄ more than C₃ plants, because C₄ plants are generally adapted for warmer situations than potential C₃ competitors. C₄ photosynthesis has a higher thermal optimum than C₃ photosynthesis, and C₄ plants are adapted to handle heat stress due to their current existence in generally hot climates. Third, for plants to exploit rising CO₂, they require sufficient supplies of soil nutrients such as nitrogen and phosphorous. On soils' very low nutrient availability, the CO₂ stimulation of C₃ photosynthesis is nil. Nutrients are often limiting in tropical soils, in part because C₄ grasses are effective at sequestering nutrients in their rootstocks and leaf litter, and

significant nutrients loss may result from fire. Hence, C₄ grasslands could maintain themselves where soil infertility prevents C₃ species from exploiting elevated CO₂. Finally, drought is a common limitation in ecosystems where C₄ species occur and here, climate change effects on precipitation patterns could be paramount. If summers become wetter, summer-active C₄ species could be favored, as long as increases in precipitation are not extensive enough to allow for woodland establishment. Alternatively, if winter and spring receive more moisture, C₃ species could be favored. Mediterranean zones that develop a summer monsoon could see a dramatic rise in the cover of C₄ species, with dire consequences for native shrub vegetation should the grasses accelerate fire cycles. Warmer temperatures and more frequent aridity will also enhance fires regimes in (sub)tropical systems to the benefit of C₄ vegetation.

Because past climate change has been associated with CO₂ rise, paleoecological studies indicate how future C₃/C₄ dynamics might develop. Between 20,000 and 10,000 years ago, temperate zone climates warmed 5–10 °C and CO₂ levels rose 30%, thereby providing a similar situation to that predicted to occur in coming centuries. Theoretically, the CO₂ rise should have had a dramatic effect on C₄ relative to C₃ distributions, because the low-CO₂ level of 20,000 years ago (180 ppm) would have been far more limiting for the performance of C₃ relative to C₄ plants. Paleoecological studies indicate that in tropical climates, there was a wider distribution of C₄ species 20,000 years ago relative to 10,000 years ago and today. In central Africa and South America, isotopic and pollen data indicate that grasslands were more widespread 20,000 years ago than at present, which is consistent with a low-CO₂ effect favoring C₄ plants. However, these regions were drier than at present, which could also explain the pattern. In temperate zones, little CO₂ effect on C₃ versus C₄ plant distribution is apparent during this time. In southwestern North America, for example, the distribution of C₃- and C₄-dominated grass and shrub vegetation appears to remain stable over the past 20,000 years, possibly because the seasonality of precipitation has also changed little over this time. In contrast to the American Southwest, substantial expansion of C₄ grasses occurred at the end of the last Ice Age on the plains grasslands of central North America. Here, C₄-dominated grasslands expanded northward between 12,000 and 8000 years ago, a time of little CO₂ change, but considerable climate warming.

Land-Use Change and C₄ Plants

Humans currently exploit much of the world's land area where C₄ plants occur; this exploitation will intensify as population and economic growth increase demands for food, fuel, and fiber. Because of this, the future of C₄ plants will largely depend on land-use decisions made by future society. In recent decades, land use decisions have been largely detrimental for native C₄ species, although a few weedy or agronomic species have done very well. Loss of natural C₄ grasslands has been severe in low-to-mid latitude areas due to the conversion of natural landscapes to timber plantations, pasture, and farms. Low-latitude pastures largely comprise C₄ grasses, but typically just a select few that are preferred by cattle. In North America,

the tall grass prairie biome has been largely replaced by row crop agriculture and pasture. Where bluestems and switchgrass (*Schizachyrium*, *Andropogon*, and *Panicum* spp.) once formed a sea of C₄ grasses stretching from Illinois to Kansas, a new C₄ species – cultivated maize – has become dominant. A second great C₄ biome lost in North America is the wire-grass/long-leaf pine savanna that once dominated the coastal plain of the southeastern USA. More than 98% of this biome was destroyed in the 1800s by grazing, logging, fire suppression, agricultural development, and more recently, timber plantations.

Overgrazing by cattle has had a particularly widespread impact on C₄-dominated grasslands in semiarid regions of Africa, the Americas, and Australia. Many of these areas have converted to dense shrublands because cattle selectively removed the C₄ biomass and the associated fuel layer needed for regular fires (Figure 15(a) and 15(b)). As a result, shrub species that were no longer suppressed by grass competition and fire were able to displace the grassland. Rising CO₂ aids the establishment of shrubs in grasslands, because it accelerates root and shoot growth of young seedlings. Woody species typically grow deep taproots below the more shallow, fibrous root systems of grasses, and once they can do this, below-ground competition between shrubs and grasses is reduced. More rapid shoot growth allows for a faster escape

from the shade of the grasses, but more importantly, it elevates the shrub canopy above the kill zones of grass fires. In coming decades, continued growth in atmospheric CO₂ levels and grazing intensity could accelerate loss of low-latitude grasslands, unless humans actively suppress shrub growth and employ management practices that favor C₄ grasses. Rather than restoring native C₄ diversity, however, grassland restoration has often relied on a limited number of selected C₄ grasses in order to improve grazing conditions for cattle.

C₄ species that will do well in the future are agricultural and invasive weeds that adapted to human disturbance. C₄ plants disproportionately make up the world's worst weeds of agricultural landscapes, and in low latitudes, they are severe bioinvasers that are capable of converting a range of landscapes to exotic C₄ grasslands (Figure 15(c) and 15(d)). In the presence of human-caused fires, exotic C₄ grasses are able to intensify wildfire regimes to the detriment of many types of native vegetation. These grasses rapidly colonize disturbed landscapes and with their high productivity, can quickly produce fuel loads that drive hot, killing fires. With more widespread disturbance and natural resource exploitation, future decades will provide greater opportunities for weedy C₄ species to expand and suppress natural vegetation in both C₃- and C₄-dominated ecosystems.

Figure 15 Photographs illustrating the potential fate of native C₄ grasslands and tropical forests in a changing global environment. (a) A C₄ range land with high cover of C₄ desert grasses and sporadic shrub cover, in western Texas. This landscape is representative of much of the rangelands of the southwestern USA prior to 1800. (b) Shrub domination of former C₄ grassland in west-central Texas, USA. (c) Invasion of C₄ grasslands into pristine rainforest in New Caledonia. The C₄ grassland (light area) replaced the forest after a fire created the triangular patch on the left side of the ridgeline. With the next fire, this patch will expand and further reduce the forest area. Reproduced from Sage RF and Kubien DS (2003) *Quo Vadis C₄? An ecophysiological perspective on global change and the future of C₄ plants. Photosynthesis Research 77: 209–225*, with permission from Springer. (d) An exotic C₄ grassland of weedy *Saccharum* spp. that has spread into forested uplands in northern Oahu, Hawaii, USA. Note how the forest is being broken into patches and isolated trees on the hillside in the middle of the photo.

Exotic C₄ Grasses and Tropical Deforestation

Through the use of fire, humans have been major agents of vegetation change for more than 2 million years. The most significant impact of burning has come in the past few thousand years, when humans increasingly used fire to maintain and expand agricultural lands. As a result, many of the natural C₄ grasslands and savannas of the world are derived from human-caused fires. In recent decades, the introduction and spread of exotic C₄ grasses has become one of the more pervasive threats to biodiversity in tropical forests and savanna. African C₄ grasses that are well adapted to human activities are the leading threats, and many of these are introduced as pasture grasses. In Central and South America, the C₄ grasses *Melinis minutiflora*, *Panicum maximum*, and various *Pennisetum* species have become widespread pests because of their ability to rapidly colonize wet soils cleared for farming or grazing, after which they establish highly flammable swards that kill all other species through crowding or burning. In Southeast Asia and Indonesia, and on many Pacific islands, the C₄ grass *Imperata cylindrica* has become a serious problem for similar reasons. Compared with the original diversity of hundreds to thousands of plant species per hectare in a mature forest, weedy grasslands are dominated by one or two species of C₄ grass.

Although the major cause of tropical deforestation has been clear-cutting for timber and agricultural development, weedy C₄ grasses contribute to deforestation by promoting destructive fires and preventing forest regeneration. The high

productive potential of the C₄ pathway allows weedy C₄ grasses to rapidly spread into these disturbed areas and establish swards that facilitate frequent burning. After repeated burn cycles, soils lose fertility due to nutrient volatilization in smoke, leaching, and nutrient sequestration by the C₄ biomass. Climates over grass landscapes are drier than forests (C₄ vegetation transpires less than C₃ forests), and trees become too infrequent to provide seeds for natural reforestation. Establishment of forest seedlings becomes difficult, if not impossible and succession is arrested in the grassland state. To avoid these problems, clear-cutting is discouraged in favor of sustainable, low-intensity harvesting. In the presence of C₄ exotics, however, even small amounts of logging can set in motion autocatalytic grass-fire cycles that cause unintended (cryptic) deforestation (Figure 16).

The objective of low-intensity logging is to mimic natural gap dynamics by creating small openings that quickly return to forest. In the absence of C₄ grasses, forest recovery is rapid because seed rain from the surrounding trees quickly establishes seedlings that fill the gap within decades. If exotic C₄ grasses can instead establish in the gap, the successional trajectory can be substantially different because of their ability to quickly generate flammable conditions. In areas with human activity, invasion of C₄ grasses into logged gaps is likely, because weedy grasses can spread from parent populations in previously disturbed areas and along roads and logging paths. Seeds of these grasses can be carried into gaps by logging equipment or even on clothing. Once established, the next critical phase is ignition, which is typically promoted by

Figure 16 A conceptual model of forest conversion to exotic C₄ grassland following low-intensity logging. In the absence of C₄ grasses and fire, the forest will regenerate in open patches created by logging. In the presence of invasive grasses and fire, autocatalytic grass-fire cycles can become established, which eventually convert the landscape to an exotic grassland. Reprinted from Sage RF and Kubien DS (2003) *Quo Vadis C₄? An ecophysiological perspective on global change and the future of C₄ plants*. *Photosynthesis Research* 77: 209–225, with permission from Springer.

human action such as the discarding of cigarettes. Ignition probabilities are higher in grass patches because they readily dry, unlike forest interiors. The first fire is often small but intense, enhanced by downed woody debris from the logging operation. Seedlings of regenerating trees are typically killed by the fire, and the fire kills forest vegetation on the edge of the patch. Grasses quickly colonize the newly killed forest margins, enlarging the patch (Figures 15(d) and 16). This promotes a second fire causing further patch enhancement, followed by additional fires within a few years of each other as long as humans provide an ignition source. Each successive fire increases the probability of subsequent fires and forest loss, because the microclimate over larger grass swards is warmer and less humid, thereby causing more extensive drying of adjoining forests (Figure 16). Also, as grass swards enlarge and coalesce, fires can spread much farther from a single ignition source. Eventually, forests become fragmented and forest patches decline in size, with consequent reduction of the seed rain from forest species. These trends are difficult to reverse, because forest regeneration is inhibited by the lack of tree seeds, reduced soil fertility, and a dryer regional climate, and so the weedy grasslands persist on the landscape. Although forest loss following low-intensity logging is slower than clear-cutting or pasturing, the end result can be the same unless people understand the process and take steps to avoid it by preventing C₄ grass establishment and fire.

Summary and Conclusion

C₄ photosynthesis is a polyphyletic solution to challenges imposed by reductions in atmospheric CO₂ and increasing aridification that occurred over the past 35 million years. In C₃ plants, the low atmospheric CO₂ levels of recent geological time promoted substantial inhibition of photosynthesis by photorespiration in hot conditions, particularly if water was also limiting. C₄ plants overcame these limitations by localizing Rubisco in the BS compartment into which CO₂ is concentrated. As a consequence, C₄ plants are highly productive, aggressive competitors under conditions promoting photorespiration in C₃ plants. This improved performance has enabled native C₄ species to dominate hot, open landscapes of low latitudes, and warm temperate regions receiving summer rain. It has also enabled invasive C₄ grasses adapted to human disturbance to become severe weeds, with important consequences for tropical biodiversity. Where humans disrupt forest cover and allow grass establishment, they establish conditions where invasive C₄ grasses can accelerate fire cycles and alter soil chemistry. In many locations, diverse tropical forests are replaced by grasslands dominated by a few aggressive C₄ species. Because natural C₄-dominated grasslands and savannas often occur on more productive landscapes, they too have been heavily exploited for agricultural purposes, resulting in habitat loss and impoverishment of the native C₄ flora of the Earth. Unfortunately, this

loss is disproportionately impacting the global biodiversity of C₄ plants, since there are only 7500 C₄ species on planet Earth.

Glossary

Biogeochemical processes The chemical, physical, geological, and biological processes that govern the composition of the biosphere.

Biogeography The study of life over space and time.

Countryside The increasing fraction of the Earth's surfaces whose ecosystem qualities are strongly influenced by humanity.

Countryside biogeography The study of life over space and time in areas of substantial human activity.

Human-dominated ecosystem An ecosystem where human presence and activities strongly influence living and nonliving ecosystem components.

Introduction

The word “countryside” generally elicits images of Anglo-American cottage communities nestled within a landscape of woodlands, pastures, and gardens. As landscape painting developed in seventeenth-century Dutch art like Bruegel’s *The Harvesters* (c. 1565), the imagined countryside was epitomized in European representations such as Haytley’s *The Brockman Family at Beachborough* (c. 1774–1776, **Figure 1**). These artistic genres framed popular western notions of idealized “landscape” and “countryside” as the harmonious coexistence of people, agriculture, and nature. However, “countryside” as an ecological term must be separated from idyllic depictions, cultural nostalgia, and European stately settings to include all of the Earth’s surfaces whose ecosystem qualities are strongly influenced by humanity (Daily, 2001). Countryside encompasses different biomes such as tropical forests, arctic tundra, and even underwater seascapes. With virtually all ecosystems impacted to a greater or lesser degree

by human activity, it is clear that the planet is human dominated (Ellis *et al.*, 2010; Halpern *et al.*, 2008).

Yet human-dominated ecosystems are rarely continuous regions of urban settlement, agriculture, or fishing grounds; instead, the majority of these ecosystems comprise mosaics of roads and buildings mixed with gardens, agricultural plots, areas grazed or harvested, and remnants of native habitats. The majority of the planet can therefore be classified as countryside, with varying proportions of nearly natural, seminatural, and heavily human-affected habitats. Given the trajectory of human population growth and increasing consumption per capita, the fate of biodiversity will be decided in the countryside.

A fundamental tool for understanding the interplay between living and nonliving ecosystem components is biogeography, the union of biology, geography, and history. In a broader sense, biogeography studies biological variation in space and time at genetic, morphological, physiological, behavioral, demographic, and ecological levels.

Clarification of Concepts: From Islands to Countryside

Island Biogeography

Countryside biogeography was developed to update and expand the fields in which it is rooted, primarily MacArthur and Wilson's theory of island biogeography (MacArthur and Wilson, 1967). Island biogeography has made a substantial contribution to theory and practice of ecology, evolution, and conservation biology.

Despite its name, island biogeography has been applied beyond island systems where areas are naturally or anthropogenically isolated. For instance, climatic conditions can isolate biological communities at the peaks of mountains, geologic variation can create "islands" of different soil chemistry, and succession often isolates floral (and therefore faunal) communities. Agriculture transforms landscapes creating natural habitat fragments or "islands" in a "sea" of human-dominated habitats. Marine environments experience variable temperature zones and light regimes based on depth, segregating habitats into underwater "islands" of habitat for some species.

Island biogeography has been critical to the development of species-area relationships and community assembly theories, but has proven insufficient for real-world applications in many situations. Island biogeography and its corollaries immediately introduce biases deep within their theoretical and empirical approaches by dismissing the "sea" or "matrix" as inhospitable habitat for the organisms in question. The consequence has been a focused effort on studying life in areas seemingly untouched by humans. This *a priori* human valuation of ecosystem components, especially as a binary of hospitable/inhospitable habitats, ignores the fact that nearly every cubic meter of the biosphere has been impacted by humans (Vitousek *et al.*, 1997).

The assumption that biodiversity only exists as a shadow of its former state outside of the so-called native habitat was only challenged once biologists began surveying and encountering organisms that were not human inquilines persisting in the long term in areas that might have been thought hostile to them. The existence of populations of numerous species completing their life cycles – possibly in modified or novel states – in the "sea" of agricultural plots and seminatural habitats, to say nothing of urban areas, has called into question the generality of island biogeography and demanded a closer examination of expanding human-dominated landscapes as a possible refuge for a substantial portion of biodiversity (Ricketts, 2001). Island biogeography is a useful theoretical construct that in some situations can predict species equilibria with reasonable accuracy (Bush and Whittaker, 1993) and can help us to better understand patterns, processes, and mechanisms operating in the countryside, and has served as a jumping off point for further investigation.

Vicariance Biogeography

Countryside biogeography is also partially founded on principles from vicariance biogeography. Generally applied to less dispersal-prone taxa, vicariance biogeography attempts to explain the distribution of biodiversity through time and space

by examining isolation and reconnection through geologic and climatic phenomena (Nelson, 1974).

Biological variation must now cope with separation and reconnection of habitats by human-created physical barriers (e.g., paved roads, crop rotations, deforestation, and bottom trawling), corridors (e.g., bridges, causeways, and hedgerows), chemical barriers (e.g., spraying for pesticides, use of fertilizers, and endocrine-disrupting pollution in waterways), stochastic barriers (e.g., nuclear disasters, oceanic oil spills, and fires), and biological barriers (e.g., regional and local extinctions of prey and mutualism partners, species invasions, population manipulation through feeding and harvesting, and human-induced changes in animal behaviors). Many barriers for some are bridges for others and permit range expansion and connection between populations.

Conservation Biogeography

The state of the environment has rallied biogeographers to redirect the relevance, aims, and values of modern biogeography toward the conservation of biodiversity by developing the field of conservation biogeography. Conservation biogeography has been defined as "the application of biogeographical principles, theories, and analyses, being those concerned with the distributional dynamics of taxa individually and collectively, to problems concerning the conservation of biodiversity" (Whittaker *et al.*, 2005, p. 4). Conservation biogeography is the product of biogeography and conservation biology and can be generalized as a contemporary field that uses biogeography to calculate and reduce rates of species extinction mainly through the design and placement of natural reserves with the goal of conserving species diversity.

The importance biogeography has played in conservation biology and the environmental movement is undeniable, but scientific visibility of biogeography has waned with the development of new fields. The goal of conservation biogeography is to revitalize the discipline and reaffirm the importance of biogeographical principles to current and future conservation efforts, while attempting to strengthen biogeographic theory and our overall knowledge of life on the planet. Conservation biogeography is different from countryside biogeography by explicitly championing a political goal – preventing species extinctions.

Countryside Biogeography

Countryside biogeography is the study of the distribution of biological variation over space and time in human-dominated ecosystems. Countryside refers to the growing fraction of terrestrial and marine habitats whose ecosystem qualities are strongly influenced by humanity. On land, the countryside includes terrain dedicated to agriculture, rural, and urban settlements, and the pockets of seminatural habitats in a variety of sizes and configurations existing in human-dominated landscapes (Figure 2). In water, virtually no area remains pristine, making marine ecosystems, coastal zones, and freshwater systems critical areas of study in countryside biogeography (Figure 2).

Figure 2 The planet is human-dominated and poorly protected. Global human impact on marine (Halpern, *et al.*, 2008) (a) and terrestrial (Ellis, *et al.*, 2010) (b) ecosystems is extensive, with approximately 75% of the planet's ecosystems strongly influenced by humanity. Moreover the extent of global protected areas is scant (Coad, *et al.*, 2009; Agardy, 1997; Sheppard, 2010) (c) and (d). Relative pie chart sizes for marine and land surfaces are proportional to their global surface areas. Impact score in (a) was calculated by summing 17 anthropogenic drivers including fishing, nutrient input, pollution, transport, and invasive species. Semi-natural label in (b) includes residential woodlands and inhabited treeless lands. Wildland in (b) includes protected areas and treeless lands. Protected areas in (c) and (d) include designated protected areas, many of whose management and effectiveness is unknown.

Countryside biogeography is explicitly inclusive of all ecosystem components (including native habitats, novel ecosystems, domestic and feral plants and animals, human populations, and the services provided by nature to human beings, including quality of life). It focuses on forecasting changes in biogeography in tandem with changes in land use, human populations, and climate.

In the wake of humanity's expansion and domination of the planet, wilderness is fading away on land and in the water, making the objectives of countryside biogeography progressively more relevant. Assuming that human impacts intensify as currently projected, countryside biogeography will be pivotal to answering three increasingly urgent questions. First, what sorts of ecosystems and their components (e.g., species, populations, and biological communities) will exist over the coming decades and centuries? Second, what sorts of ecosystems and their qualities (e.g., ecosystem functions and services) do we need and want – and how do we decide? And third, how, and to what extent, can we achieve

our goals? Answering these questions will depend heavily on countryside biogeographic investigation of the following related questions:

- What species or functional traits confer advantages or disadvantages for coping with human-induced environmental change?
- How will human-induced changes in biogeography alter the functioning of ecosystems in the future?
- What role will countryside biota and human-dominated ecosystems play in the provisioning of ecosystem services that support human well-being?
- Are existing tools (ecological theory, remote sensing, interdisciplinary models for forecasting environmental change) up to the task of predicting changes in biodiversity and ecosystem functioning?
- What practical measures can be taken to increase the capacity of human-dominated ecosystems to sustain biodiversity and provide ecosystem services to society?

To investigate these questions, countryside biogeographers utilize empirical and theoretical frameworks in concert with established ecological and evolutionary theory. Mainly through comparison of human-modified habitats with near-pristine baselines, countryside biogeography has revealed that high amounts of biodiversity can thrive in some human-dominated habitats (e.g., Gibson *et al.*, 2011; Mendenhall, 2011; Mendenhall *et al.*, 2011). These findings, along with new theories, provide scope to harmonize human activities with the conservation of biodiversity (Daily, 2001; Pereira *et al.*, 2004; Pereira and Daily, 2006; Mendenhall *et al.*, 2012). Empirical studies in countryside biogeography have shown that biodiversity is affected by a range of human activities, by the configuration and sizes of native and human-modified habitat patches, and by the physical structure of native and seminative ecosystem elements (Mendenhall *et al.*, 2011; Sekercioglu *et al.*, 2007; Daily *et al.*, 2001, 2003; Horner-Devine *et al.*, 2003; Daily, 2001; Ricketts *et al.*, 2001; Ranganathan *et al.*, 2008).

Furthermore, countryside biogeography ideally aims to measure changes in ecosystems beyond species numeration and diversity counts by quantifying ecosystem functioning (Mayfield *et al.*, 2006) and the services provided by nature to society. A growing number of studies are identifying the explicit links between changes in biodiversity, ecosystem functioning, and human well-being, but the complexity inherent in these connections hinders fast or extensive studies (Balvanera *et al.*, 2006; Winfree and Kremen, 2009). Nonetheless, tools that aid in the valuation of these connections in human-dominated ecosystems are being developed and tested around the world as countryside biogeography gains momentum (Kareiva *et al.*, 2011; Watts *et al.*, 2009).

Human-Domination of the Earth's Ecosystems

Human Effects on Ecosystems

Human effects on ecosystems have altered the course of life. Though far too complex a topic to cover in this article the authors summarize the human effects that directly influence biogeography. The main negative actions that change biogeography are habitat alteration, toxification of ecosystems, species invasions, overexploitation of natural resources, and changes in global biogeochemistry. These actions are driven by the expansion and intensification of growing human enterprises, overpopulation and continued population growth, overconsumption, and the use of environmentally damaging technologies. The extent and potency of these actions and drivers are to a greater or lesser degree the determining influence on living and nonliving components of the biosphere, including the most pristine places on the planet.

The Myth of the Untouched Ecosystems

Ecosystems are complex units made of perpetually changing components. Historically, ecosystem change generally happened slowly with few changes observable within a human lifespan. Owing to human activity, the current pace of change appears to be at its greatest in 65 million years – since Earth was struck by an asteroid, extinguishing the dinosaurs and

many other organisms. Humans have created a world where rapidly occurring changes cover expansive areas. Despite this, many environmental and political institutions continue to attempt to preserve or restore “nature” in a mythical untouched state.

Currently 3–4% of the planet has been set aside in terrestrial (~13% of all terrestrial surfaces) or marine-protected areas (<0.05% of the ocean's surface area) (Agardy, 1997; Coad *et al.*, 2009; Sheppard, 2010). Similarly, “wildlands” have shrunk to 25% of the total terrestrial cover and less than 4% of the world's oceans have “very low human impact scores” (Figure 2). Protected areas, wilderness, and relatively pristine waters have enormous biological, economic, and cultural value, but their extent is dwarfed by the expanding portions of the planet dedicated to the human enterprise of food production and impacted by our other activities. Moreover, protected areas, “wildlands,” and “pristine” waters are not exempt from human activity and many, on closer examination, are and have been human-dominated for many decades or centuries.

Human-Dominated Ecosystems

Human-domination implies that the presence and activities of people exert a determining influence on living and nonliving components of an ecosystem, not control over nature. In an attempt to propose a threshold for “human-dominance” we classify an ecosystem as human-dominated if the influence by human activities is obvious and measurable to scientists upon preliminary observation. Beyond this threshold there are many gradients of human activity intensity, and studies that span and account for such gradients will be useful to inform how biodiversity responds to various degrees of human dominance.

Human-Dominated Landscapes

The most obvious characteristics of human-dominated landscapes are the physical alterations (Figure 3). In terrestrial ecosystems the majority of human-dominated landscapes are

Figure 3 A gradient of major elements in human-dominated ecosystems: native and seminatural elements, agriculture or harvest areas, and human settlements and structures. Very rarely do ecosystems contain absolute regions of a single element type and most are usually heterogeneous, especially when less simplified ecosystem element types are used.

significantly influenced by agriculture. Almost half of the terrestrial land surface is dedicated to human food production. Rangelands account for two-thirds of that and croplands a third (Figure 2). As complex variables of population size, available arable land, per capita consumption, maximum yields, and food distribution interact, they result in agricultural intensification and annual net expansion of land dedicated to food production (Tilman *et al.*, 2001; Green *et al.*, 2005; Perfecto *et al.*, 2009).

The second major land cover to consider in human-dominated landscapes is human settlements. The global extent of towns and cities is relatively small, with rural villages covering 6.5% of all land surfaces and urban settlements 1.25% (Figure 2), but their influence on ecosystems is extremely potent. Human structures create obvious changes. The construction of Tokyo, Delhi, and New York City obviously displaced many local natural populations and created habitat for rats, pigeons, cockroaches, and other human inquilines, but scattered buildings and homes in rural areas are also important. Human infrastructure also fragments or bridges wild populations with roads and telecommunication lines acting as filters that restrict or enhance the movements of species, populations, and individuals. Moreover, human settlements bring exploitation of resources, invasive species, pollution, and changes in regional climate.

Human-Dominated Seascapes

Humans occupy and influence marine ecosystems differently than landscapes. To most people, the ocean is one big biological soup. We have only fuzzy ideas about how many marine species are out there, where they can be found, and how our actions affect them. This is exacerbated by the fact that marine biology and biogeography are severely understudied compared with their terrestrial counterparts, so that no clear estimate of global marine diversity yet exists (Sala and Knowlton, 2006), though the Census of Marine Life aims to fill this fundamental knowledge gap (Yarincik, 2005). Despite these shortcomings we do know that ecological principles apply underwater and that human influences are changing marine biogeography. Moreover, human activity has reached the farthest corners of the sea and many marine ecosystems (especially coastal ones) are dominated by humans. Characteristics of a human-dominated seascape include eutrophication and pollution, physical alteration of habitat, changes in other biogeochemical processes (e.g., climate change and ocean acidification), and changes in marine food webs because of direct harvesting of sea life.

Human Influence and Biodiversity

The Sixth Extinction Wave

Extinction is the greatest process altering modern biogeography. The number of species today is thought to be the largest in the 3.7-billion-year history of life (Rohde and Muller, 2005). In recent history, negative human impacts on ecosystems have ushered in the “sixth extinction wave” – a mass extinction event whose magnitude cannot yet be calculated because it is ongoing and the first to occur during the

existence of *Homo sapiens* (Jablonski and Chaloner, 1994; Barnosky *et al.*, 2011; Ceballos *et al.*, 2010). Current species extinction rates are estimated to be 100–1000 times their prehuman levels in well-known taxa (Pimm *et al.*, 1995; Millennium Ecosystem Assessment, 2005). The magnitude of species extinction levels is greatly affecting biogeography and being played out in human-dominated ecosystems. The degree to which biogeography is altered by extinction is extensive, especially when considering that species extinction is only the cusp of even greater losses of biodiversity at the levels of population diversity, genetic diversity, community structure, and ecosystem function.

Species Richness and Diversity

Biogeography fundamentally relies on the categorization and ordering of biodiversity into units that can be measured, compared, and contrasted. Biologists categorize and order the natural world to make meaning of biogeography. The concept of a species is the oldest, most popular, and most debated biological unit to describe biodiversity and biogeography. Since Aristotle through to the Middle Ages, the Enlightenment, and up to the present, the concept of a species has undergone countless transformations (Wilkins, 2009). In fact, an exact universal working definition is likely to never exist because of the growing number of organisms and populations that continue to defy all proposed taxonomic, reproductive, or genetic definitions. The “species problem” is still stimulating to some, but ultimately trivial – with most fields of biology tailoring definitions for purposes of human understanding on a taxon-by-taxon case and using species or other taxonomic units when it makes sense (Ehrlich, 1997; Kelt and Brown, 2000). Unfortunately, this has been largely miscommunicated, leading to the misconception that biodiversity and species diversity are equivalents. This mishap has been described as “biology’s biggest blunder” and has stunted clear understanding of the state of biodiversity and biogeography (Woodwell, 2010).

Despite the artificial difficulties with the species concept, quantifying biogeography using species as units is always the first tool ecologists turn to because of its efficiency – counting species is far faster and easier than identifying and tallying populations or piecing together interaction webs. The species concept is a particularly useful unit for countryside biogeographers who are largely interested in comparing biodiversity’s responses to human influences. The first measure is usually species richness, or the number of different species in a given area, which is later followed by an index of species diversity, which incorporates species and their abundances within an area. Species richness and diversity are deployed first in countryside biogeography, but, ideally, countryside biogeography also measures biodiversity using ecosystem components that determine function.

Population Diversity

Along with species, a key unit of biodiversity is the population. Populations are not without their own definitional problems, but generally present a more meaningful measure

of biodiversity than species (Ceballos and Ehrlich, 2002). Populations are generally defined as geographical entities within a species, which are distinguishable either ecologically or genetically (Ehrlich and Daily, 1993). That a species cannot go extinct until all of its populations have gone extinct indicates that there is considerable amplification between these levels of biodiversity. Rough estimations assess population extinction rates to be 200–4000 times greater than global species extinction rates (Hughes *et al.*, 1997). The extinction of populations affects genetic diversity. Genetic diversity is tightly linked to population diversity and refers to the total number of genetic characteristics in the genetic makeup of a species. Population connectivity, size, and distribution greatly affect genetic diversity and a population's potential to adapt to changing environments.

The extinction of populations is sometimes countered by the creation of new populations by human influences. Through human-induced physical, chemical, stochastic, climatic, and biological alterations to ecosystems, populations can be split either ecologically or genetically; they can be manipulated by feeding, hunting, facilitating or preventing disease, or reintroduction; or their movement to new locations can be intentionally or unintentionally assisted. Despite the difficulty in quantifying and monitoring population diversity over space and time, its use as a biological measure is generally more informative for understanding ecosystem change than species diversity.

Community Assemblage and Structure

Species-specific population responses to human activities determine regional species pools or ecological communities. Individual communities within a region are frequently a limited subset of species from regional pools. The notion that communities are limited in their membership was first proposed by Elton using three criteria that excluded an organism or allowed it entry into a community (Elton, 1927; Roughgarden and Diamond, 1986). The first criterion is an organism's physiological ability to persist in the physical environment where a community occurs. These physical components include climate, nutrients, and light; but under the framework of countryside biogeography they can also include infrastructure, noise pollution, chemical compounds, artificial light, and human land use. The second important factor limiting community membership is dispersal capability. The failure to reach potentially suitable habitat limits community membership, but human activity can both facilitate and hinder the movement of organisms across all spatial scales. The third element limiting community membership is species interactions, or community structure. Community structure defines organisms' roles within a community, their ability to persist, and thus their contributions to vital functions.

Classic examples of community structures are food webs, where producer–consumer and predator–prey communities are linked. Existing community structures have the potential to exclude organisms; for example, a predator may be excluded from a community if the prey sources it depends on are absent because of physical, dispersal, or other community structure limitations. By contrast, interactions can also boost community membership. For example, plants and corals that

enhance the structural complexity of an area and create habitats can permit other species to join a community. The same structural enhancement can be achieved with crop selection and configuration, such as areca nut, coffee, or fruit and timber plantations (Ranganathan *et al.*, 2008; Mendenhall *et al.*, 2011; Daily *et al.*, 2003). Finally, organisms interact with abiotic factors in their environments that are critical to many ecosystem processes, such as water and nutrient cycling. Countryside biogeography includes community properties (assemblage and structure) and ecosystem function as meaningful biological measures to examine the distribution of life in the context of human activity and land uses.

Ecosystem Function, Ecosystem Services, and Natural Capital

It is the collection of organisms, their environment, and all of their interactions with living and nonliving factors that result in the innumerable processes that determine the functioning of an ecosystem. In an attempt to quantify the most valuable ecosystem components and functions for human life support, ecologists, economists, and policymakers use the term “ecosystem services” to refer to the myriad of goods and services provided by species interactions within an ecosystem. From a countryside biogeography perspective, ecosystem services are the positive products and processes that derive from organisms interacting with each other and the nonliving components of their environments that either directly or indirectly benefit humankind. Species diversity, population diversity, community assemblage, and community structure are the cascading levels of biodiversity that create and maintain the elements of the biosphere necessary to support human life.

Many interactions can be harmful to human life and well-being. For example, forest remnants provide roosting habitat for the common vampire bat (*Desmodus rotundus*) that may spread disease and harm livestock; increased contact with African elephants (*Loxodonta africana*) has resulted in loss of crops, property, and human life; predator populations feed on livestock; and approximately 2.5 million people are envenomed and 100,000 are killed annually by poisonous snakes worldwide (Chippaux, 1998; Graham *et al.*, 2005; Wohlgenant, 1994; Hoare, 1999).

Despite these ecosystem “disservices,” most would agree that mass extinction will have an irreversible and overwhelming net negative effect on humanity. The dangers of biodiversity loss include, but are not limited to, reduced production of food, fuel, and fiber; exacerbated climate change and more severe weather events; increased disease; runaway pollution of air and water; and the elimination of the many aesthetic, cultural, and psychological facets that make life worth living (Millennium Ecosystem Assessment, 2005; Bratman *et al.*, 2012). Countryside biogeography and related fields that explicitly consider human components of ecosystems are appropriate tools for measuring the trade-offs between human enterprises, ecosystem disservices, and ecosystem services to inform land use and policy decisions in a sustainable manner (Kareiva *et al.*, 2011).

Countryside biogeography is linked to economics, politics, conflict, and human needs and desires because all these occur within the biosphere. To articulate the value and functioning

of the biosphere's life support systems, the concept of natural capital has gained popularity in today's global capitalist economy (Costanza *et al.*, 1997; Daily, 1997; Wackernagel, 1999). Thinking of ecosystem elements as natural capital from which flow beneficial goods and services has increased understanding of the value of biodiversity and ecosystem processes in political and economic spheres where decisions affecting human activity and, correspondingly, biogeography are made (Clark *et al.*, 2001). In concert with ethical arguments for preserving nature, the valuation of ecosystem services and natural capital has become a key strategy for solving the environmental crisis.

Case Studies of Countryside Biogeography

Early Countryside Biogeography

The first studies to quantify biodiversity in human-dominated ecosystems, beyond understanding the ecology of pests or domesticated plant and animals, were conducted in farmland communities in Australia, Europe, and Mexico. As early as 1925, ecologists were anecdotally describing biodiversity in human-dominated landscapes (Barnard, 1924), but it was not until the early 1990s that rigorous countryside biogeography studies were being conducted and communicated.

Early and influential studies were from Australia. One was a survey in southeast Queensland, Australia conducted over a period of 5 years in diverse coastal farmland. The authors performed 20 standardized surveys and encountered 131 bird species in a landscape "substantially cleared for agriculture, other rural use and residential occupation" (Leach and Hines, 1993). Though the authors do not provide context for comparison with historical frequencies of avifauna, they conclude the study by stating that the human-dominated "district supports a rich diversity of bird species" (Leach and Hines, 1993). Another Australian countryside biogeography study took place in northeast New South Wales in an intensively grazed landscape with less than 20% remaining tree cover, approximately 85% of which was on private land (Barrett *et al.*, 1994). This study surveyed birds, but kept careful track of woodland area size and species observations and linked observed species richness with available woodland habitat. This linking of observations with habitat allowed for an early example of a concave decay function between human land use and a biodiversity index (Figures 4 and 5).

Simultaneously across the globe, English ecologists were turning their attentions to the conservation value of semi-natural habitats in the farmed countryside. The European approach to countryside biogeography brought with it political organizations concerned with conservation of biodiversity, food security, and the preservation of a traditional way of life. In the early 1990s the long established Joint Nature Conservation Committee (JNCC) and affiliates began an initiative to engage scientists, policymakers, agriculturists, and the general public over the English and Scottish countryside's biological, cultural, and political importance. The concern put forth by members and affiliates of the JNCC concentrated on the disappearance of European traditional, low-intensity farmland. Numerous countryside biogeography reports and findings

Figure 4 The effect of area of woodland patch size on the mean number ($\pm$ SE) of bird species (within 1.2 ha transects, 294 in total) in a rural landscape of New South Wales. Woodland patches were divided into six size categories: > 400 ha ($n=77$), 101–400 ha ($n=79$), 51–100 ha ($n=39$), 21–50 ha ($n=43$), 6–20 ha ($n=35$), and < 6 ha ($n=21$). There was a significant difference in the mean number of species in different sized patches (Kruskal–Wallis, $H=11.61$, $df=5$, $p<0.05$). This difference was less significant when open-country species were excluded ($H=10.62$, $df=5$, $p<0.06$). Reproduced from Barrett G, Ford H, and Recher H (1994) Conservation of woodland birds in a fragmented rural landscape. *Pacific Conservation Biology* 1(3): 245–256, with permission from Surrey Beatty and Sons Pty Ltd.

Figure 5 Three hypothetical decay functions are presented between human activity intensity and biodiversity. Top curve is a concave decay function, dashed line is a linear decay function, and bottom curve is a convex decay function. The amount of biodiversity retained under each decay function varies markedly, with the concave decay function (top curve) permitting high biodiversity retention under low and moderate human activity intensities.

from European conservation organizations and various scientific meetings and forums were produced in the early 1990s (Bignal and McCracken, 1996).

In addition to work in Australia and Europe, early studies of biogeography in tropical countryside were being carried out in Mexico. For example, Eric Mellink surveyed birds and rodents in the San Luis Potosi Plateau countryside of Mexico and found agricultural systems to support substantial biodiversity (Mellink, 1991a, b). Shortly thereafter a detailed study of Los Tuxtlas in southern Veracruz, Mexico, was conducted by Alejandro Estrada and his team. They demonstrated that many rainforest species persisted on farmland in biodiverse tropical regions. In two studies by Estrada, the team surveyed for bats and nonflying mammals in 45 and 35 variably sized forest fragments, respectively, and 20 agricultural plots of cocoa, coffee, citrus, allspice, and mixed crops. They estimated that 77% of the bat and 44% of the nonflying mammal species were found outside of tropical rainforest habitat and were at least partially using farmland (Estrada *et al.*, 1993, 1994). These and other earlier comparisons of species richness across variable human land-use intensities in the Mexican countryside set the stage for later works examining biodiversity in other biomes.

Soon after the publication of studies and reviews by Australian, European, and Mexican scientists, countryside biogeography studies started peppering conservation biology literature and were included in many conservation-focused management schemes (Benton, 2003). Moreover, in retrospect, many authors acknowledged that studies seemingly unrelated to the field of countryside biogeography had actually been conducted in human-dominated ecosystems. For example, all of Brown's comparative studies on the population biology of desert rodents took place on sites that had been grazed at some point in time (personal comm., Brown, 1989). Many of these studies were conducted, analyzed, and communicated under the paradigm that biodiversity would generally be greatly reduced at the earliest threshold of human influences (Figure 5). Early countryside biogeography studies began to cautiously test the assumption that human-dominated ecosystems were inhospitable. At the same time, scientists began to realize that the human landscape provided interesting settings to investigate ecosystem resilience, resistance, and evolution. Finally, early countryside biogeography studies began to face the reality that not all biodiversity can, or will, persist in the coming decades.

Tropical Countryside Biogeography in Southern Costa Rica

Not until 1997 was "countryside biogeography" formally coined, despite the long-standing interest in Europe and elsewhere. It first appeared in an article in the proceedings of the 1997 Forum on Biodiversity (Daily, 1997). In this article, preliminary results of the tropical countryside biogeography of birds in Coto Brus, Costa Rica were presented.

The in-depth studies performed in the Coto Brus Valley of southern Costa Rica are among the investigations that have had the largest contribution to understanding biodiversity in human-dominated ecosystems (Gardner *et al.*, 2009). In Coto Brus, work has spanned six major taxonomic classes of mammals, birds, reptiles, amphibians, arthropods,

and herbaceous plants (Daily *et al.*, 2001, 2003; Ricketts *et al.*, 2001; Hughes *et al.*, 2002; Horner-Devine *et al.*, 2003; Mayfield and Daily, 2005; Brosi *et al.*, 2007; Santos-Barrera *et al.*, 2008). The results from these works have influenced ecological theory and land-use practices across biomes – helping develop countryside biogeography into a fully-fledged field of inquiry to be tested and replicated in other regions.

Because of the depth in which it has been examined there, Coto Brus Valley has become a flagship study system for countryside biogeography. Coto Brus Valley has a long history that includes human influences stretching back at least 3000 years. First it was heavily influenced by indigenous populations until the end of the fifteenth century, at which point it was left to regenerate until the mid-twentieth century (Clement and Horn, 2001). In the early 1950s, 45 Italian immigrants colonized Coto Brus Valley under the leadership of Vito Sansonetti (Sansonetti, 1995). After that, rapid colonization and deforestation ensued in the area. By 2000 the population of Coto Brus had grown to over 43,500 inhabitants and the tree cover in the study area dropped to approximately 30–40% (Daily *et al.*, 2001; Sansonetti, 1995; Mendenhall *et al.*, 2011).

The landscape now mostly consists of small-scale farms that raise cattle and maintain sun coffee, banana, plantain, pineapple, bean, corn, sugar cane, or yucca. Farms are rarely dedicated to a single activity and the hilly topography prevents the use of industrialized methods. A single farm rarely exceeds 5 ha and trees persist on nearly all properties in clusters or patches that weave across the landscape along valleys, hilltops, roads, and property boundaries. Within the landscape is a small Biological Reserve that is home to the Organization for Tropical Studies Las Cruces Biological Station. The reserve protects approximately 260 ha of primary and secondary premontane tropical wet forest (Holdridge, 1979). Work in Coto Brus Valley has concluded that substantial floral and faunal biodiversity exists on farmland at considerable distances from the forest reserve (Figure 6).

Like most initial studies of biogeography, the first countryside biogeography in Coto Brus Valley used bird surveys. In 1995 and 1996 surveys conducted in eight variably sized forest fragments and 13 open habitats on farmland agreed with previous work conducted in Australia, Europe, and Mexico that substantial avifaunal diversity was capable of using agricultural habitats in tropical countryside landscapes (Daily *et al.*, 2001). These findings sparked a second, expanded study in 1998 that systematically surveyed birds at 53 independent locations – corroborating the results (Hughes *et al.*, 2002). When 27 surveys of terrestrial mammals returned the same patterns, the message was clear: a high amount of biodiversity persists in the human-dominated landscape of Coto Brus. Additional studies have provided clear evidence that these patterns were not restricted to birds and mammals (Figure 5) and continue to shed light on the responses of many taxa at multiple levels of biodiversity, including an optimistic decay function where biodiversity and humanity coexist (Figure 6).

Biogeography in Ancient Tropical Countryside

Since the groundwork of the 1990s, numerous studies have been published that show high biodiversity persisting in

Figure 6 Distribution of species diversity in the Costa Rican countryside compiled from eight studies in Coto Brus, Costa Rica. Forest elements include the Las Cruces Forest Reserve and surrounding forest fragments embedded in the Costa Rican Countryside. Number of species representing each taxon in parenthesis. Images are of a single species represented in each study. Bird data from Mendenhall CD, Sekercioglu CH, Oviedo Brenes F, Ehrlich PR, and Daily GC (2011) Predictive model for sustaining biodiversity in tropical countryside. *Proceedings of the National Academy of Sciences of the United States of America* 108(39): 16313–16316, and Mendenhall C, Ehrlich P, and Daily G (2012) Improving estimates of biodiversity loss. *Biological Conservation* 151(1): 32–34. <http://www.sciencedirect.com/science/article/pii/S0006320712001115>; bat data from Mendenhall, *et al.*, in progress; non-flying mammal data from Daily GC, Ceballos G, Pacheco J, Suzan G, and Sanchez-Azofeifa A (2003) Countryside biogeography of Neotropical mammals: Conservation opportunities in agricultural landscapes of Costa Rica. *Conservation Biology* 17(6): 1814–1826; reptile and amphibian data from Santos-Barrera G, Pacheco J, Mendoza-Quijano F, *et al.* (2008) Diversity, natural history and conservation of amphibians and reptiles from the San Vito region, southwestern Costa Rica. *Revista de Biología Tropical* 56(2): 755–778, and Mendenhall *et al.*, in progress; butterfly data from Horner-Devine MC, Daily GC, Ehrlich PR, and Boggs CL (2003) Countryside biogeography of tropical butterflies. *Conservation Biology* 17(1): 168–177; moth data from Ricketts TH, Daily GC, Ehrlich PR, and Fay J (2001) Countryside biogeography of moths in a fragmented landscape: Biodiversity in native and agricultural habitats. *Conservation Biology* 15(2): 378, and plant data from Mayfield M and Daily G (2005) Countryside biogeography of Neotropical herbaceous and shrubby plants. *Ecological Applications* 15(2): 423–439, and Mendenhall and Oviedo Brenes, in progress.

countryside, including Indonesia (Waltert *et al.*, 2004), Africa (Naidoo, 2004), and India (Chundawat *et al.*, 1999). Despite the increasing number of studies, the question of extinction debts remains (Tilman *et al.*, 1994). Extinction debt is the extinction of a species because the remaining area of habitat after modification is not sufficient to allow for long-term persistence. In the context of Coto Brus Valley, it is possible that observed patterns of high biodiversity in farmland may be populations slowly going extinct over generations because the remaining area of habitat cannot support them long term. The uncertainty associated with extinction debts is of great concern for the future of biodiversity in human-dominated ecosystems. One way of getting a glimpse into the future is to look to ecosystems that underwent modification in the past.

A 2008 study of the ancient tropical countryside of Karnataka, India, has yielded insight into extinction debt in

human-dominated ecosystems. The Indian countryside of Karnataka has been continuously cultivated for more than 2000 years. The landscape is typical of many tropical regions with small-scale farms spatially intermixed with tree elements of various shapes and sizes. The agriculture supports extensive areca nut palm, cashew, rice, and peanut plantations – with land cover configuration remaining relatively constant for more than 200 years (Ranganathan *et al.*, 2008). The study again centered on ecology's best-known taxon, birds, and surveyed for species in 30 independent locations equally distributed among land-use types. From the 114 observed species, 96% were observed outside of intact forest remnants – with some of India's most charismatic bird species, like the Great Hornbill (*Buceros bicornis*) and Malabar Gray Hornbill (*Ocyrceros griseus*), found in areca nut palm plantations. Specifically, a strong relationship with increased structural complexity of human-dominated habitats was

Figure 7 Forest bird species richness vs. tree height diversity in the ancient tropical countryside of Karnataka, India. All species richness measures are estimated using the bootstrap species estimator. Five land covers are specified as follows: A, areca nut palm; C, cashew; F, intact forest; P, production forest; and S, shrub. Reproduced from Ranganathan J, Daniels R, Chandran M, Ehrlich P, and Daily GC (2008) Sustaining biodiversity in ancient tropical countryside. *Proceedings of the National Academy of Sciences of the United States of America* 105(46): 17852–17854.

found to support more forest species (Figure 7) (Ranganathan *et al.*, 2008).

The persistence of biodiversity in tropical ancient countryside suggests that patterns observed in the Neotropics and Europe are not artifacts of extinction debts soon to be paid or low regional species pools, respectively. The equilibrium states of newly deforested areas, like the Coto Brus Valley, will continue to be revealed as studies dig deeper into how biodiversity is influenced by human activities, but insights from Karnataka, India, suggest these patterns are not necessarily temporary.

From Land to Water

Terrestrial ecosystems have always been disproportionately represented in ecological studies despite the greater global extent of marine ecosystems. Countryside biogeography has also been subject to ecology's terrestrial bias. Currently we do not know of any studies that directly apply the countryside biogeography approach to a human-dominated seascape. This may be due, in part, to the different ways in which humans use the land and sea. Historical ecology has revealed profound changes in the abundance and diversity of marine life as a result of human activities (Jackson *et al.*, 2001; Pandolfi *et al.*, 2003; Kappel, 2005; Lotze *et al.*, 2006). Unlike agricultural and urban landscapes, the impacts of human activities on the seafloor and the ocean's volume through fishing, bottom-trawling, pollution, and transport are rarely visible. Because the majority of

marine systems are generally unseen (and therefore understudied), the principles of countryside biogeography developed in human-dominated landscapes should be applied with care to the oceans.

Even though pioneering investigations of countryside biogeography in marine ecosystems have yet to be conducted, a growing number of studies are underway. Studies of the heavily human-dominated waters of the Mediterranean Sea and Hawaii provide examples of how some of countryside biogeography's concepts may be taken from the land to the water.

The distribution and composition of the Mediterranean Sea's biodiversity have been directly shaped by human activity since ancient times. The sustained influence humanity has exerted on the Mediterranean through habitat alteration and harvesting for thousands of years is now compounded by the modern impacts of industrialized fishing and coastal development, pollution, eutrophication, climate change, and the introduction of invasive species (Coll *et al.*, 2010). Despite these human influences, high biodiversity persists within the Mediterranean with over 12,000 plant and animal species estimated to reside in the region (Coll *et al.*, 2010). We do not, however, have a clear understanding of how these species are responding to increasing human activity.

There is evidence that charismatic and sensitive species like the monk seal, loggerhead and green sea turtles, and many seabirds have undergone range constrictions or abandoned breeding areas, but fishing and hunting records have indicated that other species have remained stable (Coll *et al.*, 2010). In particular, the Mediterranean harvest of a number of small, short-lived species like the spotted mantis squid (*Squilla mantis*), sardines (*Sardina pilchardus*), bogue (*Boops boops*), and red mullet (*Mullus barbatus*) appears to be sustainable (Caddy and Surette, 2005).

In the heavily used waters surrounding the Main Hawaiian Islands, a study has shown that substantial biodiversity persists in heavily fished oceans (Figure 8). These accounts of biodiversity in the human-dominated seascapes of Hawaii and the Mediterranean Sea are early results suggesting that as on land, substantial marine life can coexist with humans.

Methods and Future Directions

Species Traits and Human-Dominated Ecosystems

The predictive nature of countryside biogeography encourages ecologists to forecast biodiversity's trajectory in response to human activities. Identifying genetic, physical, or behavioral traits of species or populations that confer fitness (the ability to survive and reproduce) advantages or disadvantages in a human-dominated ecosystem is a powerful tool because we can infer similar responses from other species and populations with shared traits. The ability to generalize findings across biomes and to distantly related taxa is critical to modeling how biodiversity will respond to changes in human activity, rather than experimenting on each species and population individually. For instance, a trait often taken as a measure of fitness is clutch size (number of eggs laid) of a bird or reptile

Figure 8 Mean fish biomass by consumer group per location around Main Hawaiian Islands. “Inaccessible,” “remote,” and “accessible and populous” locations are sorted in order of increasing local human population density (lowest left, highest right). Error bars represent SE of total fish biomass at survey sites within each location. Reproduced from Williams ID, Walsh WJ, Schroeder RE, *et al.* (2008) Assessing the importance of fishing impacts on Hawaiian coral reef fish assemblages along regional-scale human population gradients. *Environmental Conservation* 35(3): 261–272, with permission from CUP.

in a single breeding event (Jetz *et al.*, 2008; Shine, 2005). Clutch sizes can be used as a means to compare distantly related species or separate closely related species (or even populations) (Jetz *et al.*, 2008). For example, populations of House Sparrows can be distinguished by clutch size: tropical populations lay 2–3 eggs per clutch, whereas temperate populations lay 4–5 eggs, reflecting general patterns in clutch sizes of the tropical and temperate bird communities to which House Sparrow populations belong.

Such differences and similarities in traits can shed light on species’ potential advantages or disadvantages in human-dominated ecosystems. Moreover, species interact with each other, and one species’ success can trigger another’s success. Such as the case in Ghana, where the small royal or ball python (*Python regius*) is flourishing in concert with rodent infestations (Gorzula *et al.*, 1997). Lumping and linking organisms based on traits, rather than taxonomic relationships, permits a bioassay approach, or the use of multiple organisms or species to sort observed patterns, processes, and mechanisms.

The trait-based approach has been used in ecology for decades to understand how physical, behavioral, and genetic traits affect fitness in variable environments. Traits can include the concept of a guild – usually a group that exploits the same resource in a similar way and similar to the concept of an ecological niche (Simberloff and Dayan, 1991), behavioral syndromes (Sih *et al.*, 2004), trophic levels, morphology and

life form, or life history traits (e.g., home range/territory size, reproductive capacity, and activity patterns). Traits can help or hinder fitness in the face of human-induced environmental changes. A primary challenge of countryside biogeography is to identify and understand which traits confer advantages and disadvantages in human-dominated ecosystems. For example, one study found that plants that were bat-, bird-, and bee-pollinated and bird- or monkey-dispersed were uncommon in deforested habitats, but plants with seeds dispersed by clinging to mammal fur (“burs”) were common in deforested areas (Mayfield *et al.*, 2006). These patterns are indicative of community structure shifts between plants and their mutualistic partners in deforested areas, which may be shaping the ecosystem’s vegetation communities.

Another example is a comparative study of moths and butterflies that showed nocturnal behavior of moths to be advantageous. Nocturnality in moths permitted greater use of agricultural plots, foraging opportunity in distant forest fragments, and possibly better dispersal capabilities. This was because microclimate was homogenized across the countryside at night versus relatively extreme daytime differences between areas with and without extensive tree cover, which created barriers for diurnal butterflies (Daily and Ehrlich, 1996). Traits-based approaches may help narrow the possible trajectories of future extinctions, colonizations, and evolutionary paths of organisms in human-dominated ecosystems.

Evolution in the Countryside

Biogeography and human activities shape evolutionary paths of life on the planet. One of the most powerful ways humans affect evolution through their activities is by the removal of species and populations. Extinction of a species is not only the removal of an organism forever, but it is also the removal of its evolutionary potential. All future life will be derived from those able to exist in human-dominated ecosystems. The evolutionary bottleneck of the human-induced sixth extinction wave is currently irreversible – with little hope of sensationalized science fiction ideas of cloning or miraculous reanimation of extinct species. Similarly to the Cretaceous–Tertiary extinction event 65 million years ago that cleared the evolutionary playing field for mammals, our actions are determining the planet's future occupants.

In addition to the grave impact species extinction will have on evolution, population extinctions also cause bottlenecks altering the course of evolution. Human activity is altering the distribution of genes over space and time. For example, the reduction of African cheetah (*Acinonyx jubatus*) populations has caused such a tight genetic bottleneck that virtually no genetic variation exists among extant individuals, which makes inbreeding unavoidable and increases the species' vulnerability to disease and environmental change (O'Brien *et al.*, 1983). Conversely, positive population changes in both size and range of many species can also alter their evolutionary paths by increasing mutation rates and providing new evolutionary contexts for mutations to fail or succeed. Factors relating to gene flow, such as dispersal, temporal and spatial isolation, and changes in population size acutely impact evolution. Unfortunately, our understanding of these deep processes is limited, which makes it a key area of current and future study within countryside biogeography.

Remote Sensing

Perhaps one of the most important tools in modern biogeography is remote sensing. It is increasingly common for ecologists to use aerial and satellite sensor technologies to detect and classify objects on earth – including land and marine surfaces, the atmosphere, subterranean geologic characteristics, and floral and faunal community components. With the accessibility afforded to scientists and nonscientists through Google Earth and other virtual globe, map, and geographical information systems our collective knowledge of how the planet changes is unprecedented. The use of such tools coupled with hyperspectral imaging sensors, advanced spectroscopic and laser imaging, light detection and ranging technology, and geodetic data collection facilitates the rapid assessment of ecosystem change.

Mathematical Models and Theory

Countryside biogeography's theoretical foundations rely heavily on the fields in which it is rooted. Many theories in ecology already account for community responses to invasion, responses to disturbance and succession, and fluctuations in biogeochemical processes. Appropriate modifications of some theories have been conducted. For example, species–area relationships

have been adjusted to account for gradients of habitat hospitability (Pereira and Daily, 2006; Pereira *et al.*, 2004) and the permeability of different human-made habitats have been incorporated into metapopulation dynamics (Ray *et al.*, 2002).

There remain, however, considerable portions of ecological, evolutionary, sociological, and economic theory that have yet to incorporate effects of human-dominated ecosystems into their frameworks. For example, there has been very little work looking at how human-dominated ecosystems affect species' predator–prey, host–parasitoid, or mutualistic interactions. Also, the genetic consequences of habitat alteration and toxification of the planet are poorly understood from the perspectives of genetic drift, genetic mutation/recombination rates, and evolutionary consequences. And, finally, there remains considerable scope to develop theories that articulate how fluctuations in biodiversity and biodiversity-driven ecosystem services will interact and change human populations, well-being, societies, and enterprises.

Practical Strategies to Enhance the Conservation Value of Countryside Habitats

Despite the presentation of countryside biogeography in this piece as an apolitical framework, it is our understanding that most will (and should) practice countryside biogeography with the goal of conserving and protecting biodiversity in the long term. We acknowledge that there will be trade-offs and not all species or populations will survive into the future. Perhaps one of the most effective ways to ensure our survival and maintain our ecosystem-driven life-support systems is to control our own population growth through education, women's empowerment, and harnessing economic forces.

An equally vital action is to reduce per-capita consumption by the already rich and promote the conservation value of countryside and other habitats. Enhancement of the countryside can be done both locally and globally. At local scales even the conservation of narrow strips of trees around rivers and property borders, small patches of native grassland, or reduced use of coastal enclaves have been found to abate the decay of biodiversity in human-dominated ecosystems (Mendenhall *et al.*, 2011; Karp *et al.*, 2011). At the global scale, the countryside can be enhanced through the reduction of chemical inputs, drastically reducing carbon emissions, increasing the number of protected areas, and creating national and global policies that account for the full ecological costs of food production practices and other human activities. Finally, strategic land- and ocean-use decision making that adequately weighs the short- and long-term trade-offs between human activities and biodiversity-driven ecosystem services will be critical. Without all of these actions, the society we know may perish in the sixth extinction wave.

Effects of Ecotones on Biodiversity

Salit Kark, The Hebrew University of Jerusalem, Jerusalem, Israel, and University of Queensland, Brisbane, QLD, Australia

Published by Elsevier Inc.

Glossary

Beta diversity Also called species turnover, beta diversity refers to the change in species as one moves across habitats, communities, or ecosystems.

Divergence-with-gene-flow model of speciation

A model explaining the process of species formation (speciation) in which new species diverge in the face of gene flow, the movement of genes within a group that results from mating with immigrant individuals.

Ecotone A sharp transition zone between two or more different ecological communities or regions.

Ecotone effect The pattern of increased species richness (number of species) and abundance

in ecotones and the occurrence of unique ecotonal species.

Edge effect The effect of the juxtaposition of contrasting environments on an ecosystem.

Geographic information systems (GIS) A computer-based system for creating and managing spatial data and associated attributes. It enables the capture, storage, retrieval, analysis, and display of spatial (location-based) data.

Remote sensing The science and art of obtaining information about an object, area, or phenomenon through the analysis of data acquired by a device that is not in contact with the object, area, or phenomenon under investigation (e.g., *via* a satellite image).

Concepts and Terminology

Ecotones are areas where ecological communities, ecosystems, or biotic regions coincide. They often occur in areas of steep environmental transition, along environmental gradients. In these transitional regions, the environment rapidly shifts from one type to another based on abiotic (e.g., climatic) or biotic (e.g., community structure) factors (Holland *et al.*, 1991; Kent *et al.*, 1997). The origin of the word “ecotone” is in the Greek roots “oikos” (home) and “tonus” (tension). Many different definitions and terms have been used in the literature to describe ecotones and areas of ecological transition. These include boundary regions, borders, meeting zones, transitional zones, tension zones, zones of intermingling, and zones of transgression (Kent *et al.*, 1997). The definition often relates ecotones to more homogenous areas found on both sides of the transition or to the landscape as a whole. Ecotones can occur in both terrestrial and aquatic systems, and cover several spatial scales, ranging from large spatial-scale ecotones, where biomes meet to local-scale transitions, such as mountain treelines (Gosz, 1993; see Figure 1). These areas are sometimes considered to be dynamic zones of interaction between communities, which are unstable over time (Kent *et al.*, 1997). As suggested by Odum (1953), they do not simply represent a boundary or an edge; the concept of an ecotone assumes the existence of active interaction between two or more ecosystems with properties that do not exist in either of the adjacent ecosystems. Ecotonal regions show a diversity of boundary types that range from natural boundaries (e.g., altitudinal and latitudinal transitions) to human-generated ecotones, sometimes termed anthropogenic ecotones (e.g.,

forest clear-cut edges or urban ecotones) (Lloyd *et al.*, 2000), as shown in Figure 1.

Early work on the Effects of Ecotones on Biodiversity

Since the late 19th century, there has been interest in boundary regions and edges of ecological systems. A conceptual ecological framework for the study of ecotones was given by Odum in 1953. Odum discussed the ecotone effect, which he characterized as increased richness and abundance in ecotones and the occurrence of unique ecotonal species. Until the 1970s, there was considerable interest in ecotones within the scientific community (reviewed by Risser, 1995). This interest subsided when a focus on more homogenous and well-defined ecosystems and communities (e.g., tropical rainforests and tundra) became common. A revival of research in the field focusing on ecotones and their effects on biodiversity was seen in the late 1980s and 1990s, with the development of new research areas, especially those of landscape ecology and of conservation biology (Holland *et al.*, 1991). Studies on ecotones in the 1980s often focused on material flow (e.g., water and nutrients) across communities and on ecosystem processes in these boundary regions (Hansen and di Castri, 1992). Much of the work focused on wetlands and on riparian zones, where land–water interfaces occur (reviewed in Zalewski *et al.*, 2001). Later work in the 1990s more directly examined the effect of ecotones on biological diversity, and especially the relationship between ecotones and processes leading to morphological divergence, patterns of genetic and phenotypic diversity, species richness, rarity, and their

Figure 1 Satellite images showing a variety of natural and human-generated ecotones at several spatial scales: (a) Ecotones in the Sahel region of Africa (see text). conservation implications (reviewed in Kark and van Rensburg, 2006).

The Measurement of Ecotones

Because ecotones can rarely be delimited by a fine line, their measurement and mapping is not simple. A wide range of research approaches and tools have been used to detect and quantify ecotones. These include, among others, simulation modeling, geographic information systems (GIS), remote

sensing, and statistical tools that enable quantification and analysis of ecotones of different types and over several spatial scales. Diverse approaches for the quantification of the steepness of gradients exist (Kark and van Rensburg, 2006). Methods for measuring and characterizing ecotones depend on the data available (e.g., quantitative or qualitative, grid- or transect-based data), with one of the simplest approaches, proposed by Womble in 1951, being the quantification of the magnitude of the first and second derivatives (rates of change in a given variable or several variables along a spatial gradient) (Womble, 1951). These approaches often examine the values

of variables in an area (e.g., a 1 × 1 km grid square) relative to its neighboring regions. The basic idea is to detect areas of sharp transition (which are referred to as boundaries or ecotonal regions) by finding the areas with the highest rate of change in the value of a given variable or several variables between adjacent squares (pixels). Specific software for the detection of boundary regions and analysis are now available (e.g., BoundarySeer: http://www.terraseer.com/products_boundaryseer.php), enabling more widespread use of advanced statistical tools for the study of ecotones (Fortin *et al.*, 2000, Colwell, 2006).

In recent years, new approaches to quantify changes in diversity across gradients and boundary regions have been developed and are being applied. Among these is a range of new beta-diversity estimates of species turnover in space (Koleff *et al.*, 2003, Mena and Vázquez, 2005). These have been developed in the past decades, since Wilson and Shmida's (1984) review on beta-diversity estimates. Beta diversity and species turnover are often used when studying gradients, and although they do not focus necessarily on ecotonal areas, they can be applied to the study of ecotones.

One of the most promising directions in ecotone and boundary measurement is the use of tools developed in other areas of science. These include fields such as physics, remote sensing, and image analysis, where substantial advancements in boundary detection and gradient quantification methods have been made. Remote-sensing tools, for example, can use data occurring over several orders of magnitude, from satellite-derived data currently available at a resolution of 0.5 m to 100 km, to electronic microscope data. Further application of these tools at multiple spatial resolutions will provide a better understanding of ecotones. Recent work has shown that remote-sensing tools can be effectively used to detect ecotones and to predict species richness and rarity (e.g., range size rarity) in ecotones, especially in mountains where environmental transitions are sharp (e.g., Levin *et al.*, 2007, Levani *et al.*, 2011).

Patterns of Biodiversity in Ecotones

Studies on patterns of biodiversity in ecotonal areas have led to a range of results. Recent work is providing increasing evidence that boundary regions between ecological communities can be highly diverse at both the within-species and community levels. Ecotones have been shown to hold especially high biological diversity over several spatial scales, at both the community level (when examining species richness, i.e., the number of species in an area, e.g., Shmida and Wilson, 1985) and at the within-species level (morphological and genetic diversity) as reviewed by Kark and van Rensburg (2006). Other studies, however, have shown conflicting results, making it difficult to generalize without carefully examining each case, community, and region. Early on, Odum (1953) pointed at high species richness and abundance in ecotones and suggested that the ecotonal community commonly contains many species that are characteristic of, and sometimes restricted to, the ecotone. In a recent continental-scale study of New World birds, Kark *et al.* (2007) examined the relationship between passeriform richness and rarity of ~2300 passeriform species in 4889 one-degree New World grid cells and the

distance of the cells to boundaries between adjacent plant-based ecoregions. They found that areas nearer to boundaries between ecoregions had more bird species, and also scored more highly in terms of species rarity. The findings of their work suggest that transitional environments harbor many rare species, in addition to high richness. At the community level, there is also some evidence for high species richness in ecotonal areas in marine systems. For example, van Rensburg *et al.*, (2009) showed at the sub-continental scale in South Africa that species richness and range size rarity at a spatial resolution of quarter degree are generally negatively correlated with distance to transition areas between vegetation communities for both birds and frogs. Areas with more range-restricted species were located significantly closer to transition areas between vegetation communities than expected by chance (van Rensburg *et al.*, 2009). Similarly, in the Gulf of Aden, Kemp (2000) found high-reef fish diversity in an ecotone harboring a unique mixing of the three distinct faunas of Oman, the Red Sea, and the Indian Ocean.

Processes Shaping Biodiversity in Ecotones

Ecotones and Evolutionary Processes

The process by which new species form is called speciation. This process is of major interest to evolutionary biologists who define three major types of speciation: allopatric, parapatric, and sympatric. These models are based on the degree of geographical subdivision between populations that lead to the formation of new species. Allopatric speciation happens in geographical isolation, and has been for many years considered the major form of speciation. Parapatric speciation occurs in adjacent populations with gene flow among them, often along clines. Sympatric speciation occurs when populations are geographically congruent, and are found in the same area. The study of ecotones has led to a better understanding of the potential importance of parapatric and sympatric speciation as mechanisms for speciation. Ecotones have been proposed to be centers of evolutionary novelty that maintain evolutionary process, and especially regions where parapatric (or sympatric) speciation processes may take place (Schilthuizen, 2000). As such, ecotones have been suggested as natural laboratories where evolutionary processes and barriers to gene flow can be examined (Schilthuizen, 2000). A review by Moritz *et al.* (2000) summarized the major models of evolutionary processes that promote diversification of rainforest faunas. They include the Gradient Model (either parapatric or sympatric), which suggests that adaptive divergence caused by selection forces occurs across sharp environmental gradients, leading to speciation even in the face of gene flow across ecotones. This means that speciation does not require isolation in cases where selection is strong enough to separate populations. This process is expected to occur especially where very different environments meet in the ecotone, for example, at the border between a dry and wet rainforest. In such regions, sharp boundaries may mean that even when gene flow continues, strong selection pressures can lead to divergence.

Support for the gradient model comes from recent research examining divergence using molecular genetic, phenotypic,

and experimental approaches (Smith *et al.*, 1997; Schneider *et al.*, 1999; Moritz *et al.*, 2000; Schilthuizen, 2000). Smith *et al.* (1997), studying the little greenbul (*Andropadus virens*), a passeriform bird in the rainforest–savannah ecotone region of Cameroon, found especially high morphological divergence in the ecotone. They proposed that when the ecotone is large enough, natural selection processes could be strong enough to generate morphological differences similar to those seen in reproductively isolated species even when high rates of gene flow occur. Their data support the divergence-with-gene-flow model of speciation (Smith *et al.*, 2000), leading them to propose that ecotones may be integral to the production and maintenance of high biodiversity in tropical rainforests. Increasing evidence suggests that ecotone regions may serve as centers for rainforest speciation. Quantification of morphological and geographic distances in olive sunbird (*Nectarinia olivacea*) populations in West African forests and ecotones revealed similar divergence patterns (Smith *et al.*, 2000). Smith studied morphological divergence in another Central African species, the black-bellied seedcracker (*Pyrenestes ostrinus*). Seedcrackers show polymorphism in bill size. A megabilled morph was found in the ecotone that specializes on a very hard-seeded sedge found only in ecotonal areas (Moritz *et al.*, 2000). This ecotonal megamorph was maintained in the population, despite high levels of gene flow with rainforest populations that had only smaller-billed morphs, owing to its selective advantage for feeding on the hard seeds. Morphological divergence between habitats across an ecotone was also found in leaf-litter skinks (*Carlia rubigularis*) in the wet tropical rainforest of Australia (Schneider *et al.*, 1999). Adult skinks occurring across sharp ecotones from open (wet sclerophyll) forests to adjacent rainforests showed large morphological and life history differences over short distances despite moderate to high levels of mitochondrial gene flow (Schneider *et al.*, 1999). Populations occurring across the ecotone had larger size differences than populations located dozens to hundreds of kilometers away that were geographically isolated millions of years ago, suggesting that in this case, and perhaps in many others that await research, speciation with gene flow may have great importance, even compared with allopatric speciation.

If boundary regions harbor unique and endemic species and alleles, this may provide support for the notion that these regions also serve as centers of speciation. If this is the case, ecotonal regions are expected to contain a preponderance of recently derived species that are yet to expand their ranges (neoendemics). Fjeldså and Rahbek (1998) suggested that more recently evolved species are concentrated in transitional ecotones surrounding the main central African rainforest. This reasoning is consistent with the finding that terrestrial ecotones sustain high morphological divergence, providing evidence that current speciation processes may indeed be taking place in these regions (Moritz *et al.*, 2000; Schilthuizen, 2000; Smith *et al.*, 1997).

Ecotones, Gradients, Species Ranges, and Variability

What might lead to higher species richness in ecotonal regions compared with adjacent areas? Evolutionary processes, as

discussed above, may be one explanation. Ecological factors may also have importance in shaping this pattern. Several authors, such as Gosz (1993) and Risser (1995) have suggested that transitional areas not only share the two types of environments of the habitats that coincide in the ecotone, but also have a unique ecotonal environment. Indeed, Odum (1953) proposed that transition zones often support a unique community with characteristics additional to those of the communities that adjoin the ecotone, although also commenting this is by no means a universal phenomenon. Studies testing these predictions show mixed results, some pointing toward the occurrence of ecotonal species, while others not finding evidence for species unique and highly abundant in ecotones. The inconsistency among studies is complicated by the fact that different species, systems, scales, and regions were used in different studies or due to methodological factors, such as differences in sampling and analysis approaches. In addition, ecotones tend to shift in space and time over several spatial scales (Gosz, 1993; Kent *et al.*, 1997), as a response to climatic variation, other environmental changes (Crumley, 1993; Neilson, 1993; Kent *et al.*, 1997), and human activity (Gehrig Fasel *et al.*, 2007). They show high spatial and temporal heterogeneity, which may serve as important factors contributing to their high genetic and species diversity (Risser, 1995). For example, multiple ecotones can be defined within and around the African Sahel (Figure 1a), depending on the scale of interest and on the definitions used (Agnew and Chappell, 2000). The different transitions (e.g., that between the Sahel and the desert to the north) experience shifts in time and space, showing high spatiotemporal variability.

Another, simpler, process shaping this pattern is that ecotones, comprising meeting areas between adjoining communities, include a combination of species from two or more community types (Risser, 1995). Ecotonal areas often comprise the edge of the range for species on both sides, where many peripheral populations occur (Shmida and Wilson, 1985; Kark and van Rensburg, 2006). An important question is whether populations occurring in ecotonal areas are viable populations that exist over time within ecotones, or rather persist temporarily due to the constant flow of individuals from other parts of their range into the ecotone areas, and are not self-sustainable over time, and will disappear if this flow is stopped. Shmida and Wilson (1985) proposed that the high number of species in transitional areas could be due to a process they called the mass effect, which is the flow of individuals from favorable to unfavorable areas. For species that reach the margins of their range at the ecotone, this effect may result in some individuals of a given species establishing in ecotonal areas where they cannot maintain viable populations, existing in sinks adjacent to larger source populations (Shmida and Wilson, 1985). This may lead to increased species richness in ecotonal areas, which is maintained by constant immigration of individuals from more favorable environments. Some evidence for the existence of mass effects can be found in the literature, yet these effects seem to be rather weak, and it is currently unclear whether they can indeed act as a major factor generating high diversity in boundary regions (Kunin, 1998).

The mass effect, however, does not predict the occurrence of unique or endemic ecotonal species or genotypes. If some

species or genotypes are characteristic of an ecotone or occur at the ecotone in higher abundances than in the neighboring habitats, as proposed above, this could suggest that some ecotone populations are ecologically viable. Several recent studies have found peak genetic and morphological diversity within species in ecotone regions, with populations in these regions harboring unique and rare alleles not found elsewhere (Kark and van Rensburg, 2006). For example, a study examining allozyme (protein level) diversity within chukar partridge (*Alectoris chukar*) populations across a rainfall gradient from northern to southern Israel found that the highest levels of diversity occur in the sharp ecotone area between the Mediterranean region and the desert, in the northern Negev area. Populations in this area not only showed higher genetic diversity based on 32 loci (proteins) examined, but also had unique and rare alleles that did not occur elsewhere across the range (Kark *et al.*, 1999). The same species also had peak levels of morphological diversity in the ecotone region based on 35 traits and 23 ratios between traits (Kark *et al.*, 2002). More studies on genetic and species uniqueness in ecotonal areas are needed to enable generalizations.

Implications for Conservation

While an understanding of the effects of ecotones on biodiversity is important for evolutionary and ecological pure science purposes, it also has many implications for conservation of biodiversity and practical decision making. There has been an interesting discussion in the literature in recent years regarding whether transitional areas are valuable for conservation (e.g., see Smith *et al.*, 2001 versus Brooks, 2001). Some scientists have argued that because ecotones hold marginal populations at the edge of the range of many species, where abundances may be lower and populations more prone to local extinctions than other parts of the range, these ecotonal areas have low value for conservation as they will not persist over time, for example, if the surrounding environments become fragmented (e.g., Gaston *et al.*, 2001). Substantial conservation attention has been given in recent years to the understanding and mapping of biodiversity patterns and the underlying processes, and toward predicting the effects of global change. Ecotone and boundary regions, where change, shifts, and variability occur naturally in both space and time, could serve as useful models for understanding, monitoring, and predicting the response of individuals, populations, and communities to changing environments (Crumley, 1993; Neilson, 1993; Allen and Breshears, 1998). In addition, while some scientists suggest that ecotone populations are more likely to be negatively affected by climate change (Gaston *et al.*, 2001), other researchers have argued that ecotonal areas sustain populations that are adapted to changing, fluctuating, and unstable environments and, as such, these populations may be better able to persist in the face of predicted change (see further discussion in Kark and van Rensburg, 2006). This is especially relevant since climate shifts are expected, according to some studies, to be rapid and extreme in boundary regions between ecosystems (Allen and Breshears, 1998). By examining changes in ecotone locations over time, these areas may potentially serve as “early warning” indicators of global changes (Crumley, 1993; Neilson, 1993). However, the response depends on the spatial and temporal scales examined

and may be a useful indicator mainly at global spatial scales and rather coarse timescales. Therefore, this area deserves further attention owing to the complexity of the factors affecting the location of ecotones in space and time.

Much research in the past decade has focused on prioritizing conservation efforts and determining what areas are most important and valuable for conservation. Two main approaches have been suggested. The first approach includes a search for biodiversity hotspots, or areas with especially high species richness, endemism, and rarity. A second approach has been to select areas that are complementary, and hold biodiversity not present in other areas. Ecotones may provide a unique opportunity to conserve both high species richness and high complementarity. Owing to their relatively small size, it may prove a cost effective strategy to further conserve ecotone regions and to explicitly include them in future systematic conservation planning, given they potentially provide a high return on investment having small area and high biodiversity. Undoubtedly, if these areas have the potential to maintain and to generate species richness as well as unique and novel species and forms, they deserve far greater research attention than they are currently receiving (Smith *et al.*, 2001). Nevertheless, conservation plans for ecotones should not be considered independent of their surrounding environments. Ecotonal regions are important for our understanding of evolutionary processes (such as speciation, divergence with gene flow, and adaptation) and ecological processes shaping biodiversity (e.g., response of populations to fluctuating environments). They may enable us to better predict the responses of populations to environmental change and to further identify previously neglected biodiversity hotspots valuable for biodiversity research and conservation.

Human-related Ecotones

While early literature discussing ecotones largely dealt with natural ecotones that are generated by environmental factors such as soils, geology, and sharp climatic gradients, recent research is increasingly including human-related boundaries. Human activity is generating boundaries that did not exist before, changing their steepness and shifting their location. These boundaries include a diversity of ecotone types, such as forest clear-cut edges, margins between built-up and natural landscapes, and human-generated features, such as lakes and plantations. Research on these human-generated ecotones and their effects on biodiversity is related to a study area that is sometimes termed “countryside biogeography,” examining biodiversity in human-dominated landscapes. Another recently developing research area that is relevant is that of urban ecology. Sharp, human-caused transitions may result from human activities such as urbanization, land-use changes, agriculture, grazing, or burning (see Figure 1). These boundaries occur at multiple spatial scales, ranging from local ecotones between agricultural plots, urban areas, and roads, and their neighboring native habitat, to large-scale ecotones such as shifting desert borders owing to desertification processes and river divergence (Figure 1). These ecotones may be either static and fixed in space or dynamic and shifting in location over space and time.

A substantial amount of work in both natural and human-related landscapes has focused on what has been called the “edge effect.” This is the effect of the juxtaposition of contrasting environments on an ecosystem. It refers to how the local environment changes along some type of boundary, or edge and how biodiversity is affected by such edges. This idea is attributed by animal ecologists to Aldo Leopold and his 1933 book *Game Management*. It encompasses a wide range of both biotic and abiotic trends associated with boundaries between adjacent habitat types, natural or anthropogenic. Much of the reference to edge effects in the recent landscape ecology literature has been related to human-caused boundaries, and especially to boundaries between forest fragments and neighboring patches of habitat that have been cleared. Again, there are no clear-cut conclusions as to the effect of human-dominated boundaries on biodiversity. The response largely depends on the type of edge and its history as well the species in focus. Its conservation implications are therefore complex and deserve further scientific attention. A vast amount of research has been done on the effect of forest edges, especially the effect of human-made fragments and their edges on biodiversity. A review of edges (Murcia, 1995) suggested there are many discrepancies in the literature, and a better understanding and search for general patterns requires a much more mechanistic approach to examine the processes underlying such patterns. In this context, there has been much effort to understand the effect of forest edges on predation, brood parasitism, and the breeding success of birds. Paton (1994) found that in the majority of studies, nest success varied near edges with an increase in both depredation and brood parasitism rates. The most conclusive studies suggest that edge effects in birds usually occur within 50 m of an edge (Paton, 1994). Since these reviews, multiple studies on dozens of species and regions have been conducted. While results show mixed patterns, small and intermediate-sized fragments of natural habitat (e.g., forest) tend to show stronger edge effects than large fragments.

Conclusions

Research on the effect of ecotones on biodiversity suggests that these areas of sharp transition are, at least in some cases, centers of high species richness, genetic and phenotypic diversity. Ecotones can sustain unique forms or species that are less abundant or do not occur elsewhere. In addition, studies suggest that ecotones are areas where some populations are diverging to new species in the face of gene flow (across the ecotone). However, these patterns are not repeated in all systems and we cannot yet say how general they are. Thus, the importance of ecotones to the generation and conservation of biodiversity, especially in the face of global climate and other changes, is an area of active research interest and potential conservation investment.

Edible Plants

Eduardo H Rapoport and Barbara S Drausal, Universidad Nacional del Comahue, Bariloche, Argentina

© 2013 Elsevier Inc. All rights reserved.

Glossary

Cultivar Cultivated variety or genetic strain of a domesticated food plant.

Domesticate Plant that has been selected by humans and adapted for use as a food crop, nutrient, fiber, or for other purposes.

Ethnobotany Study of the variety, natural history, and characteristics of the plants used by human cultures.

Food Habits

Animals, whether terrestrial or marine, have limitations with respect to the variety of species they consume. They depend on what nature offers in the place where each animal lives. Since the geographic ranges of species are relatively widespread, the individuals of a given animal species may vary their food resources in different sites of the range, according to their opportunities. For this reason, the variety of plants ingested by a given species is always greater than the variety of plants ingested by an individual or by an entire population.

Domestic as well as wild herbivores may eat a wide variety of food items, but they have clear preferences for particular plant species. Some ungulates are capable of selecting the most nutritious individual plants among those of the same species. They select forage mainly by smell, and secondarily by taste. Volatile substances in the plants may either inhibit or attract foragers, and are largely responsible for their palatability. According to Klein (1970), the nutritive value of plants available to wild ruminants depends on the stage of maturity of the vegetation, with highest nutritive quality coinciding with the initiation of growth, as well as with soil type and climate. Rapid growth in plants is correlated with high nutritive quality. Similar conclusions were reported by Gardarsson and Moss (1970) in a study of food selection by the Icelandic ptarmigan (*Lagopus mutus*). This bird consumed leaves and flowers of 8, 11, 10, and 11 species in summer, autumn, winter, and spring, respectively.

Similarly, the European hare (*Lepus europaeus*) in northwestern Patagonia makes use of 17–21 species of plants in a given season out of a total of 28 species that it consumes over the year. Table 1 provides a short sample of the variety of food consumed by different herbivorous and omnivorous mammals. The case of the Soay sheep was included to show how a domestic herbivore may restrict its diet in a species-poor environment. Of course, the range of foods ingested by other animals may vary widely. Monophagous insects restrict themselves to only one plant species, soil amoebae (*Acanthamoeba*) normally ingest five species of microscopic algae (Heal and Felton, 1970), and polyphagous, pest arthropods may feed on more than 300 species of crops and wild plants. The number of food plants eaten by humans is not far from the figures shown in Table 1.

Domestic and wild ungulates may show a copious range of food species but they focus on a few, preferred plants. A number of less palatable species are used only in time of food scarcity. Studies performed in western Argentina by Kufner and Monge showed that the rodent *Lagostomus maximus* increases the variety of its food sources in degraded habitats and during droughts.

Standards of Consumption

On an individual basis, people use a small number of plant items per day, perhaps between 10 and 20 species or products.

Table 1 The number of food plants consumed annually by different mammal species

Mammal species	Common name	Number of plant species	Source
<i>Alouatta fusca</i>	Brown howler monkey, SE Brazil	52	Galetti <i>et al.</i> (1994)
<i>Ateles</i> spp.	Spider monkey, Panama	14	Milton (1981)
<i>Bos Taurus</i>	Cattle, NW Patagonia	23	Relva (1998)
<i>Copra hircus</i>	Goat, Mendoza, Argentina	76	Dalmasso <i>et al.</i> (1995)
<i>Cebus paella</i>	Capuchin monkey, SE Brazil	73	Galetti and Pedroni (1994)
<i>Cervus elaphus</i>	European red deer, NW Patagonia	34	Relva (1998)
<i>Chiropotes satanas</i>	Monkey, Venezuela	29	Kinsey and Norconk (1993)
<i>Ctenomys mendocinus</i>	Tuco-tuco, Argentina	28	Madoeri (1993)
<i>Lagidium viscacia</i>	Vizcacha de la sierra, Argentina	21	Galende and Grigera (1998)
<i>Lama guanicoe</i>	Guanaco, Mendoza, Argentina	47	Candia and Dalmasso (1995)
<i>Lepus europaeus</i>	European hare, NW Patagonia	28	Galende and Grigera (1998)
<i>Ovis aries</i>	Soay sheep, St. Kilka Island, UK	~12	Gwynne and Boyd (1970)
<i>Pithecia pithecia</i>	Monkey, Venezuela	25	Kinsey and Norconk (1993)

A normal diet includes common vegetables, fruits, seeds (in the form of flour or oil), roots, sugar, beverages (beer, wine, colas), condiments, teas, and herbals. The number of plant species normally used by an individual over a year, however, is about 100, although this is limited by the number of edible plant items commonly offered by popular markets and supermarkets. Taking into account all the variety of greens, vegetables, fruits, grains, nuts, and condiments in an exceptionally well-provisioned supermarket, the figure (including different varieties and brands) may rise to 600, according to Duke (1992).

The stomach contents of two mummies that were found well-preserved in Danish bogs provided interesting information about the gastronomic habits of people during the Iron Age. Their last meals contained 66 different plant taxa (Godwin, 1960; King, 1966), many of which are nowadays considered as cosmopolitan weeds. Before the invention of agriculture, in the Paleolithic Age, humans were hunter-gatherers, and probably had a better knowledge of the variety of edible wild plants than modern people. This knowledge, however, has slowly been lost since the Neolithic and, in present times, is still lost after one or two generations of acculturation in aboriginal communities (Plotkin, 1993). The process of civilization goes hand in hand with the loss of knowledge, as well as with the abandonment of traditional crop varieties and the habit of gathering wild plants. But at the same time, new cultivars, coming from distant countries, are constantly increasing the variety of foods. A recent case is that of the kiwi fruit (*Actinidia deliciosa*), which originated in China and then was renamed, cultivated, and popularized in New Zealand. The roots of the ahipa (*Pachyrhizus ahipa*) and jicama (*P. erosus*), of Central American origin, have become increasingly popular in the US and Southeast Asia, especially the latter species, which has a similar texture and flavor to bamboo shoots and is used by Asian food restaurants in Western countries (National Research Council, 1989; Brucher, 1989). Rice (*Oryza sativa*), of Asian origin, is at present the most popular staple in warm countries of South America, whereas the South American potato (*Solanum tuberosum*) has become mandatory in European cuisine.

The Diversity of Food Plants

No one has compiled a complete record of edible plants for the entire world. The Food and Agriculture Organization (FAO), part of the United Nations, publishes an annual report of the production of the commercially most important foods. This list includes about a hundred species of plants. In *The Oxford Book of Food Plants* (Nicholson *et al.*, 1969), the number increases to 389 species distributed among 81 plant families. These are both locally and widely known cultivated plants. Duke (1992) estimated that North American Indians ate 1112 plant species. This figure is set at 1886 species according to Moerman (1998). More than 3000 edible species are carefully listed and commented on in the voluminous book *Cornucopia*, compiled by Facciola (1990), but in its preface Noel D. Vietmeyer suggests that there are about 20,000 edible species across the world. Probably, the most complete inventory is Kunkel's (1984) book, which lists approximately 12,560

species from 3100 genera belonging to about 400 families of flowering plants and ferns. This list, however, is being constantly enriched by the contribution of many ethnobotanical studies.

The proportion of edible plant species in slightly disturbed communities is variable. In the Sonoran Desert it is about 15%. Ona Indians from Tierra del Fuego made use of at least 6% of this island flora, whereas the Chácobo Indians in the Bolivian Amazon use 21% of their surrounding flora. Medium to highly disturbed communities may contain similar or higher proportions of edible species for human consumption. For example, in western Uruguay the proportion is 17%, in southwestern Córdoba province (Argentina) it is 19%, in the outskirts of Havana (Cuba) it is 33%, in swidden (slash-and-burn) fields of northern India it is 43%, and in experimental fields in Saskatchewan (Canada) it may reach 61% of all wild plants. Yet studies like these do not necessarily reveal the actual possibilities offered by nature, but rather the knowledge of informants or the perspicacity, experience, and fieldwork time employed by the investigators. According to the estimate that about 10% of any flora represents food resources, then 10%, or 27,000, of the 270,000 species of plants already recognized by world botanists should be edible.

Since historical times, because of written testimony, Europe has conserved people's knowledge of gastronomic matters. From the botanical point of view, the UK is probably the best-known country in the world. If we compare the floristic list compiled by Martin in 1976 with Kunkel's list of food plants, and discard the exotic species, hybrids, and other sub-specific taxa, as well as plants used only during famine times, we can verify that out of 1503 species considered, 350 are edible. In other words, 23% of the British flora is edible. Thus, we have two estimates of the possible richness of edible vascular plants – 10% and 23% – and they represent between 27,000 and 62,000 species, respectively, based on the 270,000 known at present. Because the description of the world flora has not been completed yet, the final list of comestibles will probably increase in the future.

By comparison, less than 2% of the Central American flora is eatable, based on the list prepared by Duke (1992). Possible explanations for this remarkable difference are: (1) greater taxonomic ignorance or less exploration of the natural resources – because the flora of Central America is much richer than the flora of Britain, humans may have concentrated on fewer, more abundant, and profitable plants, and disregarded the less useful ones; and (2) widespread loss of cultural heritage and environmental knowledge following the conquest and colonization by European countries.

The Most Prolific Taxa

A first, rough estimation at higher taxonomic ranks indicates that the proportions of edible species are quite similar to the proportions of common (edible and nonedible species) species present in the plant kingdom. The right-hand column in Table 2 is based on a random sample of 1790 food plants appearing in Kunkel (1984).

If the property of being eatable or palatable were randomly distributed among the different taxa, then it would be

Table 2 A comparison between common and edible Species in higher taxonomic groups (figures represent percentages of their respective totals)

<i>Taxonomic group</i>	<i>Common species (n = 270,000)</i>	<i>Edible species (n = 1790)</i>
Pteridophyta	3.9	1.9
Gymnospermae	0.3	1.0
Dicotyledoneae	69.9	75.5
Monocotyledoneae	25.9	21.6

predictable that the most numerous families of plants would contain a higher number of edible species (Table 3). This relation seems to be valid since many of the most prolific families are also among the most productive in edible plants. This is the case with the Compositae (Asteraceae), Leguminosae (Fabaceae), Gramineae (Poaceae), Euphorbiaceae, and Rubiaceae, which occupy the top positions in the ranking of both common species and edible species. The most numerous of all plant families, the Orchidaceae, however, has few edibles. Among the most suggestive cases is the number of genera in the Cactaceae family, which appears in the fourth place for edibles but is the 31st in the rank of common plants.

There is no clear relation among the ratios of number of species per genus that allows us to differentiate edible from common species. Among families with the lowest ratios are the Asclepiadaceae (8.0), Cruciferae (8.6), and Rutaceae (10.0). Families that are richer in species per genus are the Begoniaceae (255.0), Aizoaceae (208.3), and Eriocaulaceae (92.3), yet they show no evidence of having experienced a process of selection, that is, of proclivity or rejection by humans, that would have led them to speciate toward palatability or distastefulness.

Of the 389 more frequently cultivated species considered by Nicholson *et al.* (1969), the ranking goes as follows: Rosaceae (13.3% of total species), Leguminosae (8.5%), Gramineae (6.4%), Compositae (5.9%), Umbelliferae (5.4%), and Cruciferae (5.1%). They are followed by Palmae, Cucurbitaceae, Rutaceae, Alliaceae, Chenopodiaceae, Dioscoreaceae, Annonaceae, Ericaceae, Grossulariaceae, and 66 less prolific families. Kunkel (1984) states that the Rosaceae is the richest family among food plants. The analysis of a sample of 6222 items from his list confirms this assessment. Rosaceae appears at the top of the list, comprising 5.8% of the cases, insofar as Leguminosae are split into Fabaceae (fourth place), Mimosaceae (sixth place), and Caesalpiniaceae (82nd place). On the contrary, if the latter three families are considered as a unit, the Leguminosae stand in first place, comprising 6.7% of the sample. The rank of the first 30 families is shown in Table 4.

Edible Parts

Some plant genera are extremely abundant in edible species and may show particular tendencies toward a given kind of food (Table 5). For example, all of the 205 species of *Rubus* appearing in Kunkel's list provide edible fruits. Among them, there are three species whose leaves are also used as tea. Similarly, the 80 or more species of *Prunus* provide edible fruits, as also occurs with *Rosa* spp. and *Ribes* spp. The majority of *Piper* species are

Table 3 A ranking of the abundance of genera per plant family

<i>Common species</i>	<i>Edible species</i>
Compositae (Asteraceae)	Compositae
Orchidaceae	Leguminosae
Leguminosae (Fabaceae, Mimosaceae)	Gramineae
Gramineae (Poaceae, Bambusaceae)	Cactaceae
Rubiaceae	Umbelliferae
Cruciferae (Brassicaceae)	Palmae
Umbelliferae (Apiaceae)	Rubiaceae
Euphorbiaceae	Labiatae
Liliaceae	Euphorbiaceae
Asclepiadaceae	Cruciferae
Acanthaceae	Rosaceae
Labiatae (Lamiaceae)	Myrtaceae
Palmae (Arecaceae)	Araceae
Scrophulariaceae	Apocynaceae
Rutaceae	Moraceae

28. Vitaceae
29. Araceae
30. Cucurbitaceae

^aThe richest family of common edible and nonedible species, the Orchidaceae, appears in 45th place.

used as black or white pepper or as a spice for curries. *Rumex* provides 44 species with leaves used as vegetables and three species with edible roots. Of the 100 edible species of *Solanum*, 59 are used only for their fruits, 20 species only for their tubers, 14 for both fruits and leaves, six species only for their leaves, and a single species exclusively for its seeds.

Table 5 The most prolific genera of food plants

Genus	Family	Number of food species	Total number of species	% food species
1. <i>Rubus</i>	Rosaceae	205	2500–3000	7–8
2. <i>Ficus</i>	Moraceae	137	700	20

^cIncluding bulbs and rhizomes.

^dIncluding gums, latex, sugars, and masticatories.

An analysis of the data compiled by Duke (1972) for Central America indicates that 85% of the plant species are used for a single purpose, 10% have two uses, 4% have three uses, and 1% have four uses (leaves, flowers, fruits, and seeds). A similar analysis of the 350 edible species of native British flora yields slightly different proportions: 78%, 19%, <3%, and <1% for one, two, three, and four purposes, respectively. One of the exceptional cases of variability of uses is that of hops (*Humulus lupulus*). Its leaves, roots, flowers, and bark may be used as food and as condiment. The pumpkin (*Cucurbita moschata*) provides fruits, seeds, flowers, young leaves, and shoots for human consumption.

It is clear from **Table 6** that some kinds of food are scarcely used, such as bark, flowers, sap, and liquorice. In contrast, leaves (including stems, sprouts, seedlings, and shoots) and fruits seem to be the most preferred food.

Geographic Patterns of Food Plants

On the basis of a sample of 1790 species from Kunkel's list of food plants, it appears that edible herbs are more numerous

than trees, shrubs, and vines. Vines include all the climbing, creeping, and epiphytic plants. **Table 7** shows that in decreasing order of species richness, the Indomalayan regions appear first, followed by the Neotropical, Palearctic, Ethiopian, Nearctic, and Australian (or Australasian) regions. By means of a chi-square test, at a significance level $P < .05$, the Nearctic and Australian regions show greater, and the Palearctic lower, proportions of food trees than expected. The proportion of edible shrubs does not vary significantly among regions, although at a $P < .1$ the Neotropics seem to have a higher proportion than the rest of the world. The Palearctic region shows a higher and the Neotropics a lower proportion of herbs, whereas the latter region is richer in vines ($P < .05$). In contrast, the Northern Hemisphere (Palearctic and Nearctic regions) shows a significantly lower proportion of vines than the Southern Hemisphere.

According to biogeographic regions (**Table 8**), the Palearctic shows a significantly greater proportion of species that provide edible leaves, stems, and sprouts than the other regions. The Australian region is characterized by a greater

Table 7 The distribution of food plants by growth form in different geographic regions^a

Growth form	Total number of spp.	Percentages (from totals)	Nearctic (North America)	Neotropical (C. & South America)	Indomalayan	Australian	Ethiopian (Africa S. of the Sahara)	Palaearctic (Eurasia and North Africa)
Trees	504	25.9	14.3	24.9	33.9	45.1	35.4	9.6

^bIncluding bulbs and rhizomes.

^cIncluding gums, latex, sugars, and masticatories.

proportion of edible seeds, and the Neotropics by its abundance of fruit species. Of course, these differences were derived from the sample analyzed by us. For instance, the appearance of zero values for beverages from the Australian and Palaearctic regions does not mean that there are no species of this kind in their floras; they were simply not registered in our sample of 1790 species. On the contrary, the high proportion of edible fruits in the Neotropical region is repeatedly verified in ethnobotanical studies performed in different countries of Central and South America. These contrasts may be attributed to differential characteristics of seed dispersal evolution within their plant communities, as well as to prevailing cultural trends in the use of natural resources. The possibility of ethnobotanists showing biased attention toward particular kinds of food should not be discarded.

Are Edible Weeds Weeds?

The habit of gathering wild food plants has not been totally lost. Spencer maintained that “any plant is a weed if it insists upon growing where the husbandman wants another plant to grow. It is a plant out of place in the eye of man; in the nice eye of nature it is very much in place.” Many of our dearest crops, however, have originated from weeds. In the course of

time, humans learned how to profit from them. Oats (*Avena sativa*), foxtail millet (*Setaria italica* derived from *S. viridis*), chicory (*Cichorium intybus*), pak choi (*Brassica rapa*), spinach beet (*Beta vulgaris*), and many more species appeared originally as invaders in ancient cultivated fields. Furthermore, several cosmopolitan weeds, such as dandelion (*Taraxacum officinale*), garden rocket (*Eruca vesicaria*), common purslane (*Portulaca oleracea*), and shepherd’s purse (*Capsella bursapastoris*), are nowadays cultivated for the specialty food market.

After analyzing a set of 22,521 species of plants inhabiting natural ecosystems of North and South America, we concluded that 11.3% were edible. In another sample of 1264 species from seminatural communities in the temperate Neotropical region, edibles were 20.3% of the total. But if only weeds are considered (2455 widely spread species), the proportion mounts to 35.6%. This demonstrates that the degree of environmental disturbance correlates with the proportion of weeds, which in turn increases the proportion of edible food resources. This should not be surprising given that 17 of the world’s 18 most aggressive weeds provide parts for human consumption. Because weeds are so numerous (more than 10,000 species cataloged) and so abundant (averaging 1.3 and 2.1 ton ha⁻¹ in a temperate and a tropical area of northwestern Patagonia and eastern Mexico, respectively; Díaz-Betancourt *et al.*, 1999; Rapoport *et al.*, 1998), they stand

ambiguously as both enemies and potential benefactors of humanity.

The prospects for the future of food plant diversity appear to be auspicious. Further research should be conducted to manage and profit from these varied and abundant natural resources. At present, more than 15,000 species of food plants are recorded and this figure is constantly growing. Yet most of the world is fed with about 20 crops. As has been pointed out by Facciola (1990), 8000 cultivars of apples have been developed by humans, but only a handful are available in supermarkets.

Glossary

Alpha diversity Number of species within a restricted area, usually a small sample from a homogenous habitat.

Beta diversity Change in species composition from one area to another.

Ecotone An abrupt spatial transition from one community to another often caused by change in environmental conditions or in the disappearance of a dominant species like the forest limit.

Gamma diversity Total number of species within a large area or landscape encompassing a number of samples from different communities.

Mid-domain effect A hypothesis based on random distribution of species ranges within a bounded domain resulting in maximum species richness in the middle of the domain.

Source-sink dynamics Dynamics between populations that are net exporters of individuals and populations that are net importers of individuals.

When walking along an elevational gradient we see many features change as we walk upward passing through various life zones. Most dramatically it may change from a dense tropical forest that is packed with visible biological life to the snow capped tops with no sight of life. When comparing these extremes it is obvious that species richness is lower at the extreme mountain tops than in the lowlands. The striking changes in climate, plant communities, and faunal assemblages with increasing elevation have led to the formulation of many of the most widely accepted ecological concepts, including niche theory, life zones, community assembly, and insular biogeography. The interest in elevational patterns, particularly in species richness, has fluctuated over the last 100 years, but has greatly increased over the last decade as a result of the increasing interest in broad-scale patterns of biodiversity. Rigorous quantification of elevational species richness patterns from different parts of the world may prove to be the key to a much-needed understanding of broad-scale diversity mechanisms.

History of Elevational Studies

It has probably always been acknowledged, and it was clearly noted by the nineteenth century naturalists, that diversity of plants and animals was higher in the lowlands than at the mountain tops. Willdenow, von Humboldt, Darwin, and Wallace made detailed observations along altitude and noted that the stature and diversity behaved in the same way along altitude and latitude (Lomolino, 2001). In fact, Linne and Willdenow went further and actually explained the latitudinal distribution of species to be a result of elevational distributions during the Great Flood (Lomolino, 2001).

Among the first rigorous quantitative descriptions of elevational species richness patterns were works by Grinnell and Storer (1924), Whittaker (1952, 1960), and Whittaker and Niering (1965). Grinnell, known for coining the niche concept, detailed species distributions, abundance patterns, and range limits of vertebrates along an elevational transect in the

Yosemite region of the Sierra Nevada, CA, USA (1924). His study emphasized that the “amplitude of the general environment – the number and extent of distinct ecologic niches it compasses – determines the richness of the fauna, both as regards number of species, and the number of the individuals to the unit of area representing each species”. While Grinnell used elevational distribution patterns to understand niches and richness patterns, Whittaker undertook elevational gradient studies in the Great Smoky Mountains (insects; 1952), Siskiyou Mountains (plants; 1960), and Santa Catalina Mountains (plants; Whittaker and Niering, 1965) to tease apart important potential climatic drivers of species richness and abundance (e.g., water availability, soil type, temperature), and to determine the cohesiveness of communities.

Whittaker’s elevational studies tested community cohesion by contrasting the support for the two main hypotheses: Gleasonian continuum hypothesis versus Clementsian discontinuity hypothesis. The discontinuity hypothesis proposes that groups of species have a similar distribution along an environmental gradient with more or less a clearly defined transition to another group of species, i.e., that the community actually behaved as a superorganism with respect to the environment. The continuum hypothesis proposes that the individual species are distributed independently from each other and that centers and boundaries of species populations are scattered along the environmental gradient. With numerous studies, using elevational gradients as their test system, Whittaker and colleagues found that species tended to have independent range boundaries providing evidence against the discontinuity hypothesis and supporting the continuum hypothesis. These studies had an enormous impact on vegetation ecology, sparked gradient analyses, and ignited the use and development of ordination techniques and related statistical methods in ecology.

While discussing the cohesiveness of communities, Whittaker and colleagues detailed both monotonically decreasing species richness with increasing elevation and humped pattern with maximum species richness at intermediate elevations (e.g., Figure 1(a)). Grinnell and Storer (1924) determined

Figure 1 (a) The percentage of each of the three main elevational richness patterns demonstrated in the robust, informative montane gradients across the globe: nonflying small mammals (McCain, 2005); bats (McCain, 2007a, b); plants (from Rahbek, 2005, Figure 3f; plant percentages rescaled to include only these three diversity patterns); birds (McCain, 2009); and reptiles (McCain, 2010). (b) Generalized climatic model for elevational species richness, incorporating a linearly decreasing temperature gradient and a unimodal water availability gradient. Species richness is depicted in gray tones with darker tone indicating more species. The placements of generalized wet and dry montane gradients are shown below the x-axis (e.g., McCain, 2007a, b). Adapted from McCain CM (2007a) Could temperature and water availability drive elevational diversity? A global case study for bats. *Global Ecology and Biogeography* 16: 1–13.

that each group of vertebrates (bats, rodents, breeding birds, amphibians, and reptiles) exhibited a humped richness pattern with the highest species richness between 1000 and 1300 m. One important conclusion is that richness patterns found in Whittaker's studies differed among species groups (e.g., trees, bushes, and herbs; flies, beetles, and grasshoppers), whereas different vertebrate groups in Grinnell's studies showed consistent diversity trends with elevation. The combination of studying patterns in species richness and gradient analyses naturally leads to a way of quantifying the degree of change in composition of communities along a gradient, which Whittaker (1960) termed beta diversity.

After Whittaker, most attention to broad-scale patterns in diversity was focused on latitudinal gradients. This continued until the seminal work of John Terborgh on bird communities along an elevational transect in the Peruvian Andes (e.g., Terborgh, 1977, 1985). Terborgh's widely cited bird study detailed strongly decreasing richness with increasing elevation and showed support for the importance of habitat complexity, competition, and ecotones in bird diversity patterns. Thereafter, decreasing diversity along elevational clines became the accepted and assumed pattern for all taxonomic groups, that is, the elevational pattern mirrored the latitudinal pattern of diversity (e.g., Brown and Lomolino, 1998). As time passed the humped elevational patterns of Grinnell and Whittaker were forgotten, although their contributions on niches, community cohesiveness, and gradient analysis were not. Rahbek (1995) began to question the pervasiveness of the decreasing diversity pattern, which he claimed was based on very few studies that had serious sampling biases and called for more rigorous studies on elevational patterns. He presented a preliminary overview of elevational diversity patterns, and found

more support for humped richness patterns with the highest richness at intermediate elevations than decreasing patterns. After Rahbek's study in 1995 the interest in elevational patterns in species richness has increased enormously. Today, elevational gradient studies are often motivated by increasing our knowledge about broad-scale patterns in diversity and the search for global drivers of biodiversity is so urgently needed for conservation efforts worldwide. As noted by Grinnell and Whittaker, and repeated recently by Lomolino (2001) and Nogués-Bravo *et al.* (2008), the elevational gradient is ideal for doing studies on broad-scale distribution of species and species richness.

Observed Patterns and Ways of Quantifying Patterns

Two types of data are used to quantify the elevational pattern in species richness. Alpha diversity studies use local field sampling of plots along a transect usually on one mountain slope preferably with equal sampling effort at each elevational band. Alternatively, gamma diversity studies use regional data from previously collected specimens and field records for an entire mountain or mountainous region. Such regional data are often readily available and summarized in flora and faunas from mountainous areas around the world.

Unlike other broad-scale gradients, field sampling is feasible for elevational transects and together with appropriate statistical methods can give a robust richness estimate. When using museum or historical data the observed pattern may be very sensitive to the intensity of sampling. One common way to account for sampling intensity is to assume that each species is present at all elevations between the upper and lower

elevations of observation (interpolation). Interpolation can create an artificial hump in species richness along the elevational gradient if sampling is incomplete (Grytnes and Romdal, 2008). If more detailed specimen information is available, uneven sampling may be accounted for by using rarefaction or extrapolation (Grytnes and Romdal, 2008), without such information error simulations can test for pattern robustness (e.g., McCain, 2007a).

Rahbek (2005) conducted an overview of elevational richness patterns from the literature. The majority of these studies treated plants and he demonstrated that almost 50% of these studies found a humped pattern, and around 25% had a monotonic decrease with elevation. The fraction of hump-shaped patterns increased to around 70% after excluding studies that did not consider the whole gradient (Figure 1(a): plants). Rahbek's study also demonstrated the importance of scale, for example, a hump-shaped pattern is more common if a single transect is studied (i.e., alpha diversity), than if the pattern is studied on a whole mountain range (i.e., gamma diversity).

McCain has performed a series of global meta-analyses on elevational richness patterns among taxonomic groups from published studies. These and previous analyses clearly show that the observed pattern depends on the organism studied and the local climatic conditions (Figure 1(a); McCain, 2005, 2007a, 2009, 2010; Rahbek, 2005). Nonflying small mammals (rodents, shrews, marsupials) almost ubiquitously demonstrate unimodal richness patterns with the highest richness at intermediate elevations (robust, informative gradients (RIG)=54; McCain, 2005). Bats demonstrate two global patterns: half of the studies found decreasing species richness with increasing elevation and the other half found unimodal richness patterns (RIG = 12; McCain, 2007a). As stated above, Rahbek found that plants tend to show mostly unimodal richness patterns (RIG = 21; from Rahbek, 2005, Figure 3f). Birds show more variation in their elevational richness patterns: 30% are decreasing, 43% have high diversity across most of the lower portion of the gradient then decrease (low plateau in diversity; e.g., Figure 1(a)), and the final 27% have unimodal richness (RIG = 95; McCain, 2009). Finally, for reptiles 54% show a decreasing pattern, 25% have a low plateau, and 21% have a unimodal richness pattern (RIG = 24; McCain, 2010; Figure 1(a)).

Mountain regions often host a large fraction of endemic species (e.g., Orme *et al.*, 2005). Considering that isolation is an important factor for speciation; it is no surprise that fraction of endemic species tends to increase with altitude resulting in a peak in species richness at intermediate elevations above the peak in total species richness. For vascular plants in the highest mountains of the world the fraction of endemics increases linearly from the lowlands to the highest point where plants are found (around 6000 m above sea level) (Vetaas and Grytnes, 2002). This results in a peak in endemic richness around 4000 m, whereas the total number of species peaks around 1500 m. Studies on avian mountain endemics demonstrated their greatest diversity at intermediate elevations between 1500 and 3000 m, although somewhat lower on shorter mountains, even though overall diversity decreases monotonically with elevation (e.g., Stotz *et al.*, 1996). Such contrasting patterns in total species richness and endemic

species richness are most likely commonplace along elevational gradients, particularly for highly diverse groups.

Discussion of Possible Causes

Elevational gradients are invaluable for discerning between diversity hypotheses. The small spatial scale, the thousands of independent replicates on mountains across the globe of various heights and in various climates, the high variability in richness patterns among taxonomic groups, and the predictable trends in abiotic factors with elevation allow globally distributed elevational gradients to be used as natural experiments, allowing for rigorous testing of hypotheses. The causes commonly mentioned for elevational patterns in species richness are very similar to the causes used to explain other broad-scale factors in species richness. These can be grouped into four categories: climatic hypotheses based on current abiotic conditions, spatial hypotheses of area and spatial constraint, historical hypotheses invoking processes occurring across evolutionary time scales, and biotic hypotheses (e.g., community overlap (ecotones), source-sink dynamics, and habitat heterogeneity). Below the authors describe some of the most commonly asserted hypotheses and assess their current level of support.

Climatic Hypotheses

Climatic variables like temperature, rainfall, and productivity are probably the most commonly cited causes for broad-scale patterns in species richness and elevational patterns are no exception. Temperature has a simple relationship with altitude as it decreases monotonically by 0.3–0.6 °C per 100 m elevational gain. Rainfall often follows a more complex relationship with altitude and maximum rainfall is often found at intermediate elevations, but is also known to increase with elevation or be high across a broad band of low to intermediate elevations. In tropical areas the zone of maximum humidity often corresponds to the cloud zone and horizontal precipitation from low-lying clouds can significantly increase the water availability at those elevations.

Climate may affect elevational species richness patterns in several ways. First, climatic tolerances of the studied species may put restrictions on how many species that can survive at different elevations. This will have different effects on different species groups, and may be a result of their evolutionary history and niche conservatism (Wiens *et al.*, 2010). Some species groups (e.g., epiphytic plants, salamanders) are dependent on high and constant moisture, whereas others may be restricted by a certain winter temperature. As a result, different species groups will show different elevational richness patterns, exactly what was demonstrated by Whittaker's early studies and confirmed by McCain's meta-analyses. Second, species richness may depend on productivity through the number of individuals that are found in an area. Higher productivity leads to higher number of individuals, which in turn leads to higher species richness. Primary productivity is dependent on temperature and precipitation. Because rainfall in many cases increases with elevation or has a humped relationship with

altitude, highest productivity may be found in the middle of the elevational gradient in many cases. In arid or seasonally dry areas where precipitation is low at the lowest elevations, productivity may decrease with temperature because higher temperature leads to higher evaporation. This may explain differences in patterns between mountains with wet versus dry local climates so that species richness on wet mountains is monotonically decreasing with increasing elevation whereas on dry mountains richness peaks at mid-elevations (Figure 1(b)). Evaluation of this model shows very good support for bats, as all bat diversity patterns studied from dry based mountains show peaks in richness at intermediate elevation, whereas all but one study on wet based mountains show strongly decreasing bat richness with increasing elevation (McCain, 2007a). Brown and Lomolino (1998) also concluded that dry montane environments may show mid-elevational peaks in diversity across multiple taxonomic groups due to the higher water availability at intermediate elevations.

Spatial Hypotheses

Area

The classical species–area relationship is often asserted to explain elevational species richness patterns, predicting more species in elevational bands that cover more area. Most area on mountains occurs at lower elevations (Körner, 2000) but in some areas, particularly mountainous regions, steep valleys at low elevations cover less area and lead up to a large plateau at intermediate elevations and in such cases area is more extensive at mid-elevations. This variation predicts different elevational richness patterns between mountains if area determines richness and may serve as an exceptional test system for evaluating the importance of area on broad-scale patterns.

So far, very few studies have investigated the effect of area on elevational patterns in species richness. McCain (2007b) evaluated the species–area relationship across 34 globally distributed mountains. Area influences montane richness patterns to a surprisingly low degree; overall only 38% of the studies showed strong responses to area (i.e., had a significant impact on the elevational pattern in species richness). In these cases correcting for area generally resulted in changing linearly decreasing patterns to mid-elevational richness peaks, but the area effect does not appear to be consistent enough among studies to be the main driver of richness patterns (McCain, 2007b). Another important point is that the high impact of human influence in the lowlands may reduce the available area for species at lower elevations along many elevational gradients (Nogués-Bravo *et al.*, 2008)

Mid-Domain Effect (MDE)

MDE is a relatively new hypothesis for explaining broad-scale patterns in species diversity. The hypothesis predicts a humped species richness pattern when species ranges are randomly distributed within a geometrically constrained domain (i.e., base and top of a mountain). A terrestrial species range cannot extend over the top of the mountain or below the base at sea level or the lowest regional elevation. Most of the elevational studies published lately discuss the potential of MDE as an

explanatory factor. The conclusion from these results is that MDE predictions can sometimes be highly correlated with the observed pattern (e.g., Kluge *et al.*, 2006), but in the majority of the studies the fits to the model are low (Dunn *et al.*, 2007). MDE may play a role in concert with other factors such as area and climate, but are probably not the main driver of elevational richness patterns.

Biotic Hypotheses

Ecotone and Source–Sink

Along elevational gradients the distance between very different climatic zones and hence also between different communities and biomes is short. This implies that there will be short distances between optimal and suboptimal areas for many species along the gradient. This may result in a net flow of seeds or propagules from optimal to suboptimal areas. Even though a population of a species usually would not survive in a suboptimal area over time, the extra propagules received from populations in the nearby optimal areas (usually called source populations) may result in persistence of the populations in the suboptimal areas (sink populations) (Pulliam, 1988; mass effect is another term used to describe this process, Shmida and Wilson, 1985).

Source–sink dynamics will generally inflate species richness along the whole elevational gradient as new species are added locally by sink populations. This may affect elevational species richness patterns in two ways. An elevational pattern in species richness may be created by source–sink dynamics only if some areas receive more sink species than other areas. This may be the case around ecotones where more sink species may be found than in surrounding areas resulting in peaked species richness around ecotones. Studies that have looked for the ecotones specifically have difficulties in actually detecting an abrupt change in species composition or increased species richness around the assumed ecotones (Terborgh, 1985). Alternatively, source–sink dynamics may create an elevational pattern if the lower and upper part of the elevational gradient receives less sink species than the mid-elevational parts. Mid-elevational areas will receive sink populations from source populations both above and below, whereas the upper and lower part of the gradient will only receive sink species from one direction. This will create a humped pattern, with maximum species richness in the middle of the elevational gradient. Using sterile species as indications of sink species studies on plants have shown that the mass effect may be important for shaping the elevational species richness pattern (Grytnes *et al.*, 2008; Kessler, 2009).

Habitat Heterogeneity

Heterogeneity will certainly have a large effect on species diversity. It is, however, difficult to say anything general about how heterogeneity will vary with elevation. The relevant type of heterogeneity will depend very much on the species group studied and on the scale of study. For bird species that forage in forest trees or for epiphytic plants the important heterogeneity will certainly depend on height of canopy and number of strata that can be defined in the forest (e.g., MacArthur and MacArthur, 1961; Terborgh, 1977). This will generally decrease

with altitude, or be related to productivity. An opposite example can be found by looking at moisture variation at relatively small scale. At high elevations water runs in small canals creating a high heterogeneity of moisture. At lower elevations the water gathers in larger and larger waterways and at small to intermediate scales the moisture heterogeneity will increase with elevation. Owing to the difficulty in defining the taxon-appropriate habitat heterogeneity and obtaining robust field measurements, habitat heterogeneity has not been tested rigorously beyond the elevational studies of Terborgh (1977).

Historical Hypotheses

Ultimately, species richness patterns result from differences in speciation, extinction, and immigration rates. Speciation rates, extinction rates, and clade age are thought to be correlated with latitude causing the highest richness near the equator through influence from climate and/or area (Brown and Lomolino, 1998). Examining elevational gradients eliminates this problem by examining diversity patterns within a single region of potentially uniform clade ages and latitudinally similar speciation and extinction rates. The predictions of evolutionary rates have been less developed along elevational gradients, but in addition to a positive relationship between climate and evolutionary rates that may cause high evolutionary rate at low elevation; the increasing isolation toward higher elevation will work in opposite direction. Elevational trends in evolutionary rates will certainly have little effect on mountains whose biota mainly comprised organisms that have colonized from a larger regional pool (e.g., areas covered by ice during the last ice age) compared to large mountain ranges like the Andes or Himalayas that also have endemic species generated through various gradients of speciation, extinction, and climatically fluctuating range shifts. The consistency of taxonomically and thus ecologically linked climate trends on elevational gradients (e.g., small mammals, bats, birds; Figure 1) lends support not only to current climate drivers but also to past climatic affinities. It may be that the signal of highest richness on mountains – in wet and warm conditions – is because these were the conditions under which most taxonomic groups and species originated. This lends support to importance of niche conservatism in shaping the elevational gradients (Kozak and Wiens, 2010) and diversity gradients (e.g., Wiens *et al.*, 2010), which posits that modern large-scale species richness patterns result from that fact that most modern groups and species originated when the majority of the earth was experiencing tropical-like conditions and these strong affinities still exist in current climatic regimes.

Conclusions

The unique opportunities for evaluating hypotheses for broad-scale patterns along elevational gradients in species diversity have not been fully utilized to date. Comparing independent transects and searching for similarities and differences in patterns between transects and among taxonomic groups in different climates (tropics, deserts, temperate

regions), biogeographic regions (islands, continents) or between transects on mountains of different size or aspects (dry versus wet slopes) will certainly improve our understanding of mechanisms underlying broad-scale patterns in diversity. We need to develop more predictions specifically for comparisons of multiple elevational transects (as those shown in Figure 1(b)), gather robust climatic data at small spatial scales, and optimally design new elevational studies to test predictions of diversity theory. Elevational trends in other aspects of species beyond diversity may help define other important aspects of global ecological patterns. For example, studies of elevational trends in range size coupled with physiological tolerances will improve our understanding of role of climatic tolerances driving broad-scale diversity patterns (e.g., Janzen, 1967: why mountains are higher in the tropics) and the potential impacts of climate change. Similarly, understanding how biotic interactions (e.g., disease, food resources, competition) influence species ranges and abundance patterns is fundamental to understanding niche dynamics, as well as the strength of coupled responses to climate warming. For these reasons and because climatic shifts may be more rapid along the smaller scaled montane gradients, elevational gradients may be ideal for long-term monitoring of species responses to climate change.

Forest Canopies, Animal Diversity

Terry L. Erwin, Smithsonian Institution, Washington, DC, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Arboricolous Living on the trees, or at least off the ground in shrubs and/or on tree trunks.

Emergent A very tall tree that emerges above the general level of the forest canopy.

Epiphytic material Live and dead canopy vascular and nonvascular plants, associated detritus, microbes, invertebrates, fungi, and crown humus.

Hectare Metric equivalent of 2.47 acres.

Microhabitat A small self-contained environmental unit occupied by a specific subset of interacting species of the forest (or any other community).

Scansorial Using both the forest floor and canopy for movement and seeking resources.

Terra firme forest Continuous hardwood forest of the nonflooded or upland parts of the Amazon rainforest.

Introduction

The forest canopy is arguably the most species-rich environment on the planet and hence was termed the “last biotic frontier,” mainly because until very recently it had been studied less than any other place, with the exception of the deep ocean floor and outer space (Erwin, 1983). The reason for lack of study of the canopy was accessibility; and the evidence of the incredible species-richness, mainly of tropical forests, is primarily the abundance of insects and their allies. This hyperdiverse and globally dominant group has adapted to every conceivable niche in the fine-grained physical and chemical architecture of tree crowns. In the past three decades of the twentieth century, canopy biology became a mixed scientific discipline in its own right that is rapidly gaining sophistication of both approach and access. Tropical arboricolous (tree-living) arthropods were observed in the early 1800s in the “great forests near the equator in South America” and later that century were described by Henry Walter Bates. Even though Bates observed, described, and commented on the canopy fauna (as viewed from the ground and in recently felled trees), more than a century passed before Collyer designed an insecticide application technique that allowed a rigorous sampling regime for canopy arthropods. William Beebe and collaborators early in the twentieth century recognized that the canopy held biological treasures, but “gravitation and tree-trunks swarming with terrible ants” kept them at bay. Frank Chapman, a canopy pioneer (of sorts), viewed the treetops from his “tropical air castle” in Panama in the 1920s, but his interest was vertebrate-oriented, his perch was a small tower, and his observations of insects and their relatives were casual. By the mid-1960s and early 1970s, a few workers in both basic and applied sciences were seriously investigating canopy faunas of temperate and tropical forests in both the Western and Eastern Hemispheres. From the early 1980s until now, many workers have been improving methods of access and other techniques used to register, sample, and study the fauna (see reviews by Basset, Erwin, Malcolm, Moffett, and Lowman, Munn and Loiselle, and Winchester in Lowman and Nadkarni, 1995; Moffett, 1993; Mitchell, 1987). Some of these workers have found that arthropods by far make up the fauna of the canopy (Erwin, 1982, 1988, 2004; Erwin *et al.*, 2004).

Visiting and nesting birds, mammals, reptiles, and amphibians represent a mere 1% or less of the species and even lesser in the abundance of individuals in these groups (Robinson, 1986). There are no adequate measures of canopy nematodes, mollusks, or other nonarthropod microfauna groups.

What is meant by the forest canopy? Generally, the canopy, or tree crown, is thought of as that part of the tree including and above its first major lateral branches. The canopy of a single tree includes the crown rim (the leaves and small twigs that face main insolation from the sun) and the crown interior (the main trunk and branches that gives a tree its characteristic shape). The canopy fauna is that component of animal life that inhabits the tree canopy and uses resources found there, such as food, nesting sites, transit routes, or hiding places. Hence, the forest canopy is collectively all the crowns of all the trees in an area. The canopy is often thought of as being stratified into emergent individuals, one to three regular canopy strata, and an understory of smaller trees living in the shade of a more or less continuous over story. All types of forests have their own describable characteristics, from the spruce forests of Alaska and northern Canada to the pine forest of Honduras, the dry and rain forests from México to Bolivia, and the *Rinorea* and *Mauritia* forests of the upper Manu River in Perú. It is through “whose eyes” one views the community, habitat, or microhabitat that determines the scale of investigation and subsequent contribution to the understanding of the environment – the beetles, the rats, the birds, the ocelots, the investigators, or perhaps even the trees.

Canopy Architecture, Animal Substrate

A temperate forest is composed of both broad-leaved and coniferous trees, with one or the other sometimes occurring in near-pure stands depending on the latitude and/or altitude and also on soil and drainage conditions. Normally, there are few canopy vines or epiphytes and perhaps some wild grape or poison ivy vines. Soil and organic debris caches are few or absent in the tree crowns, except for tree holes which provide homes to numerous arthropod groups but few vertebrates. Temperate forests are subjected to cold and hot seasonal climate regimes, as well as wet and dry periods. Great expanses of

the forest lose their leaves in the winter months, sap ceases its flow, and the forest “metabolism” comes to a slow resting state.

The temperate forest seemingly provides a great variety of substrates for the canopy fauna, but faunas are depauperate compared with those in tropical forests. Virtually no mammals are restricted to temperate forest canopies – only a few frogs and lizards. However, many bird species are restricted to the canopies, as they are in tropical forests. Among insects, for example, the beetle family Carabidae has 9% of its species living arboricolously in Maryland, 49% in Panama, and 60% or more at the equator in South America.

Tropical forests, in contrast, have few if any coniferous trees; only forests at higher elevations and/or located closer to subtropical zones have coniferous trees. Tropical canopies are often (but not always) replete with vines and epiphytes, tree holes, and tank bromeliads, and there are soil mats among the roots of orchids, bromeliads, and aroid plants. In the early 1990s, Nadkarni and Longino demonstrated that epiphytic material is fraught with macroinvertebrates, and Coxson and Nadkarni later showed that epiphytic material is important in the acquisition, storage, and release of nutrients.

Lowland tropical forests are subjected to mild temperatures, without frost, but have both wet (sometimes severe) and dry seasons. Individual species of trees may be deciduous, but in general tropical forests are always green and there is a perpetual growing season. Substrates are constantly available for the fauna. Often, some microhabitats with their substrates are temporary in the sense that they remain in place for a season or two, but then their architectural structure collapses into a jumbled pile of organic detritus on the forest floor. Such microhabitats (e.g., a suspended fallen branch with its withering leaves) provide a home resource to thousands of arthropods in hundreds of species, many found only in this setting. Eventually, such a branch loses its dried leaves and crashes to the forest floor. However, a short distance away, another branch breaks from a standing tree and the process begins again. The arthropods of the old, disintegrating branch move to the new one. The microhabitat and its substrates are forever present across the forest; each individual branch being ephemeral. The faunal members occupying such microhabitats are good at short-range dispersal.

Exploring the Past Biotic Frontier

Until recently, it was impossible to study the forest canopy well. Getting there was the limiting factor, and even after getting there (e.g., *via* ropes) it was difficult to find the target organisms. Modern devices such as aerial walkways (e.g., ACEER, Tiputini Biodiversity Station; **Figure 1**), one- or two-person gondolas maneuvered along crane booms (e.g., in Panama at Smithsonian Tropical Research Institute (STRI)), and web-rope techniques (see review by Moffett and Lowman in Lowman and Nadkarni, 1995) now allow real-time observations, sampling, and experiments anywhere in the canopy. Inflatable rafts that suspend mesh platforms resting on the upper crown rims of several trees have provided access from above, although this technique seems more suited to botanical work or leaf-mining insects, especially epiphytes and

Figure 1 The rainforest canopy of the western Amazon Basin from the canopy walkway of the Los Amigos Biological Station.

lianas. Insecticidal fogging techniques allow passive sampling of all arthropods resting on the surfaces of canopy plants (Erwin, 1995), and suspended window/malaise traps collect the active aerial fauna. Many of these techniques have been used. However, often they were simply used as collecting devices to garner specimens for museums and/or for taxonomic studies, and for this purpose they are excellent. In some cases, ecological studies were desired, but the techniques were not properly applied and the results disappointing. It is important to first ask the questions and then design the experiments; in some cases, current canopy techniques can be powerful tools for answering questions. Unfortunately, although sampling is relatively easy, sample processing is time consuming and laborious. For canopy-fogging studies, after the sampling effort, an average of 5 years was required before published products were achieved (Erwin, 1995). The main reason for this is a lack of funding for processing the results of fieldwork, even though the field studies were readily funded. Without processing, the data inherent for each specimen are unavailable for taxonomy or ecology studies. This is an historical funding problem and one of the reasons most studies examine only a few species from few samples.

Results of Studies

Invertebrates

Recent findings by Adis in the central Amazon Basin and by Erwin in the western part of the basin demonstrated that there

are as many as 3.4×10^{10} terrestrial arthropods per hectare. A recent 3-year study of virgin terra firme forest near Yasuni National Park in Ecuador by Erwin found an estimated 100,000+ species per hectare in the canopy alone. This figure was determined by counting the actual species in the samples of several well-known groups and comparing their proportions in the samples with their known described taxonomic diversity. The predatory beetle genus, *Agra* (Figure 2), has more than 2000 species found only in Neotropical forest canopies and scattered remnants of subtropical forest canopies in southern Texas and northern Argentina. The herbivorous weevil genus, *Apion*, likely has more than 10,000 species. In only 109 m² samples of canopy column from a 1-ha plot of virgin terra firme forest near Yasuni National Park in Ecuador, more than 700 species of the homopteran family Membracidae were found along with 462 species of the beetle family Carabidae, 368 species of the beetle family Mordellidae, and 178 species of the spider family Theridiidae.

“Biodiversity” by any other name is “terrestrial arthropods” – that is, insects, spiders, mites, centipedes, millipedes, and their lesser-known allies. Forest canopy studies of terrestrial arthropods are few (Erwin, 1995). Many of these studies currently concentrate on host specificity as a herbivore or parasite that eats only one other species of plant or animal. However, there is another class of specificity that is very important in understanding biodiversity that has received almost no study: “where” species hide and rest. This is not random, but rather species-specific (Lucky *et al.*, 2002).

Terrestrial arthropods are found in “hotels” and “restaurants” or “in transit” between the two (Figure 3). Often, insects and their allies eat, mate, and oviposit in the restaurant, that is, the food source, for example, on fungi or in suspended dry palm fronds. These insects may hide during the day under debris or under barks near the fungus or on the palm debris, but they never roam far from the vicinity of the food source, except to locate new food sources when the old one has been depleted. Members of other species eat in one place and then move to cover for a resting period, that is, the hotel. An example of this is the subfamily Alleculinae of the beetle family Tenebrionidae. These beetles feed on lichens and moss on tree

trunks at night and spend the day (hiding, resting, and possibly sleeping) in suspended dry leaves elsewhere in the forest. Many species found in the forest canopy during the day (utilizing leaves, fruits, and/or flowers) hide and rest at night in the understory (e.g., various pollen-feeding beetles and the larger butterflies).

Insects particularly, and some of their allies, have adapted to nearly every physical feature of the planet, and the canopy is no exception. Many beetles have special feet for walking on leaves; some even have modified setae on their feet to slow them down on landing from rapid flight (Figure 4). Because they are in an environment with raptorial birds, lizards, and frogs, many insect species have evolved camouflage coloration. Climate is the main constraint on terrestrial invertebrates. In the temperate zones, it is the winter cold and dryness; in the equatorial tropics, it is the dry season for some and the rainy season for others, with the temperature far less of an influence than it is in the far north or south. Many herbivores must contend with plants that produce toxic chemicals or other defensive systems. All insects must also deal with other insects that predate, parasitize, or carry bacteria, fungi, or other insect diseases. Hammond, Stork, and colleagues, in their studies of insects in the Sulawesi dipterocarp forests, and Miller, Basset, and colleagues in New Guinea found much less insect diversity and richness than Erwin and his teams in the Neotropical forests. Hammond also found in southwest Asia that the canopy fauna was not as delimited from the understory fauna as it is in the Amazon Basin. Unfortunately, all these teams used different methodology; hence, much of their results are not comparable. It is certain, however, that the Old World tropical forests are not as biodiverse as those in the New World, nor are the forests of Costa Rica and Panama as diverse as those of the Amazon Basin. Disparate regional richness is one of the main problems in estimating the number of species on the planet. Another is the incredible richness of terrestrial arthropod species and the fact that scientists likely know <3–5% of them if published estimates of 30–50 million extant species are close to reality. Stork (1988) has even gone so far as to suggest that there could be 80 million species on the planet. New data from the Yasuni region of eastern Ecuador (Erwin *et al.*, 2004) suggest that even 80 million is a conservative estimate.

Figure 4 Setae of an arboreal beetle's tarsi used for landing and stopping quickly.

Vertebrates

Availability of food year-round constrains vertebrates from living strictly in canopies (see reviews by Emmons and Malcolm in Lowman and Nadkarni, 1995). Only in evergreen rainforests is there a continuous supply of food (albeit somewhat dispersed and sporadic) for phytophagous and insectivorous vertebrates. In deciduous forests, most species also forage on the ground or hibernate when food supplies are short. Almost all canopy mammals live in evergreen tropical forests, but even there most are scansorial. Timing and distribution of food resources are the critical controlling factors. Among all nonflying vertebrates, anurans and lizards and to a lesser extent snakes are the most important truly canopy creatures. Birds and bats are also exceedingly important components. All these groups except snakes account for vertebrate predator-driven evolution of the far more dominant invertebrates of the canopy. For example (as Blake, Karr, Robinson, Servat, Terbourg, and colleagues have shown), throughout the tropics ~50% of birds are strictly insectivores, whereas another 8% take insects and nectar. Morphological adaptations that allow canopy life include feet that can firmly grip the finely architected substrate of twigs, leaves, and scaly bark. Emmons, in her many articles on Neotropical mammals, demonstrated that among these animals, those with the ability to "jump" avoided wasting energy and time by descending and climbing new trees to find resources; hence, more true canopy species have this ability. This is certainly true also of frogs and lizards. However, it is the flying forms – birds and, to a lesser extent, bats – that account for most of the treetop vertebrate fauna. Physiological adaptations that allow vertebrate canopy life include the ability to subsist on diets of fruit, flowers, leaves, or insects and their allies. Among mammals, fruit eaters are dominant.

As shown by Duellman, Dial, and colleagues, among canopy anurans and lizards, nearly all are primarily insect predators. Birds are overwhelmingly insectivorous in the canopy fauna, with ~40% in the upper Amazonian and 48% at Costa Rica's La Selva Biological Station. Malcolm, in summarizing the few articles on the subject, estimates that 15% of mammal species are arboreal-scansorial in temperate woodlands, whereas between 45% and 61% exhibit this

behavior in tropical forests. In Duellman's 1990 list of anurans and reptiles from Neotropical forest, 36% are strictly arboricolous, whereas 8% are scansorial. Among birds, Blake and colleagues found that scansorial species using the understory and ground were more numerous than strictly canopy species (51% and 42%, respectively), at their site in Costa Rica.

In summary, although canopy vertebrates are important in driving part of invertebrate evolution in the forest canopy, they have not overwhelmingly radiated into or made use of the canopy, as the invertebrates have. For example, the total vertebrate fauna known at Cocha Cashu, Perú, is ~800 species (~45% of which are arboricolous or scansorial), whereas at a nearby location there are nearly 900 species of the beetle family Carabidae, of which more than 50% are strictly arboricolous. In Ecuador, near Yasuni National Park, there are in excess of 600 species of the homopteran family Membracidae in a single hectare, 100% of which are strictly arboricolous.

Conclusions

Although animals may use the air for dispersal, they live on substrate. Here, they eat, mate, hide, and transit. Forest canopies are rich in species because they offer a three-dimensional array of varying substrates that directly receive the sun's energy with little filtering. Although much has been and is being accomplished by faunal studies of the forest canopy, there is still much to do. There are missing data links between vertebrates and invertebrates and between both of these and the plant food and plant architecture on which they depend, and data are also missing on the influence of the canopy's physical features on the fauna such as microclimates (see Parker's review in Lowman and Nadkarni, 1995). Each subsystem is receiving at least some attention, but the new discipline of canopy biology is in its infancy. Is it too late? The forests and their species-rich canopies are rapidly disappearing (World Resources Institute, 1993).

Topics of current investigation include canopy insect β -diversity and measures of host specificity, the latter particularly in leaf-feeding beetles. Both areas of study were

driven by earlier, somewhat naive estimates of millions of species extant on the planet (Erwin, 1982; Stork, 1988; May, 1990; Casson and Hodkinson, 1991; Gaston, 1991). Although some of these studies may have been internally consistent within the parameters set for the estimations, no one had really got a handle on the true meaning of “host” specificity, biocomplexity of tropical forests, the influence of tropical biotope mosaics, β -diversity or what is known as species turnover in space and/or time, or the disparities of richness among continents, or even the disparity among regions within continents.

Even so, our current rudimentary knowledge indicates that we are losing hundreds, even thousands, of invertebrate species with “scorched Earth” programs such as that in Rondonia, Brazil, clear-cutting of Borneo and other southern Asian forests, and other losses in Haiti, Puerto Rico, Hawaii, the western Amazon Basin, Madagascar, and so on.

Conservation strategies are currently dominated by data on vertebrates (Kremen *et al.*, 1993; Samways, 1994); however, invertebrates are rapidly becoming sufficiently known to include them in analyses that are directed toward preservation of forest communities; to this end, the collective human conscience will soon be dealing with real extinction processes equivalent to those in the past, from the Permian to the Cretaceous. We are living at the beginning of the so-called sixth extinction crisis *sensu* Niles Eldridge of the American Museum of Natural History. Amelioration of the impact of this crisis rests on a better knowledge of the natural world around us and the development of conservation strategies that consider what we, Earth’s managers (whether we like it or not), want future evolution to look like, as so well described by Quammen (1998).

Glossary

Accidental epiphyte Plant that normally grows terrestrially but that occasionally grows to maturity in a tree crown, usually in terrestrial-like microsites such as the crotches of branches.

Bryophyte Nonvascular plant of the division Bryophyta (a moss, liverwort, or hornwort).

Cryptogam Plant that reproduces by spores or gametes rather than seeds; includes bryophytes and lichens.

Epiphyll (folicolous) Plant that grows on the leaf surface of another plant.

Epiphyte Nonparasitic plant that uses another plant as mechanical support but does not derive nutrients or water from its host.

Facultative epiphyte Plant or lichen that commonly grows epiphytically and terrestrially, usually exhibiting preference for one or the other habit in a particular habitat.

Homoiohydric Ability to maintain a constant internal water balance independent of fluctuating environmental conditions.

Lichen Composite organism consisting of a fungus (the mycobiont) and an alga or a cyanobacteria (the phycobiont) that live in a symbiotic relationship.

Mistletoe Woody parasite that taps the xylem of a tree, but is capable of photosynthesis.

Obligate epiphyte Plant that always grows on another plant for structural support, but derives no nutrients from the host.

Parasite Woody or nonwoody plant that taps into the vascular system of a host plant and derives energy or nutrients from it, often to the detriment of the host.

Poikilohydric Condition of internal water balance varying with changes in ambient humidity.

Primary hemiepiphyte Plant that begins its life cycle anchored in a tree crown and ultimately becomes rooted in the ground (e.g., strangler fig).

Secondary hemiepiphyte Plant that begins its life cycle as a terrestrial seedling, ascends a tree, and can later lose root connections with the ground, including (a) lianas, woody climbing plants with relatively thick stems that generally grow in mature habitats, and (b) vines, herbaceous climbing plants that regularly grow in disturbed habitats or forest edges.

Introduction

Definition of the Forest Canopy

The forest canopy has been called “the last biotic frontier” (Erwin, 1998). It presents a habitat conducive to the evolution of literally thousands – perhaps millions – of species of plants, microorganisms, insects, birds, and mammals that are rarely or never encountered on the forest floor. Although forest canopies have been among the most poorly understood regions of our planet, their mysteries are being explored by increasing numbers of biologists. Canopy communities are now believed to be important in maintaining the diversity, resiliency, and functioning of the forests they inhabit.

The forest canopy is a structurally complex and ecologically important subsystem of the forest. It is defined as “the aggregate of all crowns in a stand of vegetation, which is the combination of all foliage, twigs, fine branches, epiphytes as well as the interstices (air) in a forest” (Parker, 1995). The forest canopy is the primary site of gas exchange between the atmosphere and vegetation and fosters many ecosystem processes that are crucial to the maintenance and diversity of the forest as a whole (Lowman and Nadkarni, 1995).

Scope of this Article

Trees are the most obvious structural component of forest canopies. Their trunks, branches, and leaves constitute the

infrastructure of the canopy and provide mechanical support for thousands of species of arboreal plants and animals. Tree species diversity is discussed elsewhere.

Although much has been published on canopy plants, the question of the global importance of epiphytes for the biodiversity of tropical and temperate forests in general and the canopy in particular has only recently been explicitly addressed. Previous reviews of canopy biodiversity have primarily dealt with arthropods (Erwin, 1998; Nieder *et al.*, 2001; Ozanne *et al.*, 2003; Ambrose, 2004; Lindo and Winchester, 2007), or with specific subgroups of canopy plants (Kress, 1986; Rhoades, 1995). Here, the authors describe the diversity of many types of canopy-dwelling plants. Included in this article are epiphytic vascular plants, epiphytic cryptogams (nonvascular plants that include lichens and bryophytes), primary and secondary hemiepiphytic vascular plants (lianas and vines), and arboreal parasitic vascular plants. Arboreal fungi and free-living algae are so poorly known that there is little to review (Stone *et al.*, 1996). The authors place greatest emphasis on obligate and facultative epiphytes, and exclude accidental epiphytes from this article.

The term “diversity” in the following will be based on species as the unit of biological diversity, since assessment of other aspects of biodiversity is virtually nonexistent in the case of canopy plants. The authors first review the systematic distribution of canopy taxa and provide species counts based on the state of current knowledge. The authors discuss gradients

of canopy plant diversity of microsites within the canopy at various spatial scales, spanning a single microsite within a tree (e.g., twig, branch bifurcation) to regional and global levels. Biogeographical analyses of canopy-dwelling taxa are then considered, as well as some of the major evolutionary elements that have influenced their distribution and abundance. "Habit diversity" (the diversity of morphological and physiological features) of arboreal taxa will then be described. Finally, the authors discuss conservation efforts that involve canopy plants and suggest future research possibilities.

Historical Roots and Sources of Information

In 1832, Charles Darwin first described what he termed the great diversity and profusion of "parasitical plants" (that the authors now understand to have been epiphytes), which he encountered in abundance in the coastal forests of Brazil. In the late nineteenth century, the German botanist A. F. W. Schimper first described epiphytes and outlined their importance to tropical botany.

Historically, canopy studies have been dominated by people who sought the thrill of climbing and followed the lure of discovering new species. Early European explorers hired climbers and trained monkeys to collect specimens of "exotic" air-plants that grew out of reach. Pioneering work in old-growth forests of the Pacific Northwest contributed to the application of mountain-climbing techniques for safe and reliable access to the canopies of tall trees. Since 1980, the innovation of high-strength and low-cost canopy access equipment has made canopy study more viable as an option for scientific research. There are now a wide variety of access tools from which to choose, depending on the questions being addressed and the available budget (Lowman and Nadkarni, 1995). With the development of effective technological climbing methods such as the "canopy raft" and the canopy crane, and of ground-based methods such as insecticidal fogging, researchers now spend less time working on how to prudently work in the treetops and more time pondering the difficulties in recording meaningful canopy data, analyzing it, and interpreting the results.

A remarkable burgeoning of scientific interest in the canopy has occurred within the last decade. This is related to increasing concerns with such conservation issues as biodiversity, global atmospheric change, and management of tropical and temperate rain forests. The number of scientific publications on canopy structure has grown at a disproportionately rapid pace relative to the general field of biology (Nadkarni, 1994). Aspects of the canopy have been the focus of many recent symposia, scientific books, and popular articles and media.

Reviews of vascular epiphyte, hemiepiphyte, and parasite diversity have been compiled (Madison, 1977; Calder and Bernhardt, 1983; Kress, 1986; Benzing, 1990; Putz and Mooney, 1991; Williams-Linera and Lawton, 1995; Lowman and Nadkarni, 1995; Benavides *et al.*, 2005). Studies about the biodiversity of nonvascular plants and lichens have increased rapidly in the last decade (Diaz *et al.*, 2010; Rhoades, 1995; Pentecost, 1998; Keller, 2004; Snell, 2001). The biodiversity of canopy nonlichen fungi has not been well documented (D. Reynolds, personal communication).

For this article, the authors compiled the foregoing sources and searched the primary literature for additions and modifications. The authors also consulted on-line databases and communicated with numerous taxonomists and specialists to ensure that the information presented is current and accurate. To place canopy plant diversity into the context of biodiversity in a given study area, the authors compared inventories of epiphytes and nonepiphytes. The epiphyte quotient (sometimes called "epiphytic index") is defined as the percentage of epiphytes out of the total number of vascular plants in an area.

Categories of Canopy Plants

Vascular Epiphytes

Forest canopies support extensive flora that include more than 24,000 species, or about 10% of all of the tracheophytes (Kress, 1986). Vascular epiphytes differ greatly in structure, function, and fidelity to their degree of dependence on canopy versus terrestrial habitats. Ecologists recognize their important roles in nutrient cycling and in providing arboreal and terrestrial animals with food, water, and nesting materials (Nadkarni, 1994). Ecophysiologists recognize the varied structures and mechanisms that protect vascular epiphytes from drought (Benzing, 1990).

Some of the characteristics for regular occurrence on bark and associated aerial substrates are obvious (e.g., holdfast roots and wind-dispersed propagules), but others are more subtle. In an extensive review of vascular epiphytism, Benzing (1990) outlined a variety of characteristics that are exhibited by vascular epiphytes (Table 1).

Vascular epiphytes are mainly restricted to the low latitudes and within the tropics. They reach their greatest abundance and diversity at low to mid-montane elevations (Madison, 1977; Benzing, 1990). Ferns occur in higher latitudes along the margins of the Pacific, and a few hardy bromeliads and orchids occur in the mild north and south temperate zones (e.g., *Epidendrum rigidum*, *Polypodium polypodioides*, *Tillandsia usneoides*, *Fascicularia bicolor*). The most extensively colonized temperate forests are those of southeastern Australia, New Zealand, and Chile, where a variety of vascular epiphytes grow in areas protected from frost by nearby ocean currents.

Nonvascular Epiphytes

In a review by Rhoades (1995), nonvascular (or cryptogamic) epiphytes were categorized into three groups: lichens, bryophytes, and free-living algae. Although the phylogeny and composition of the two plant groups considered here are very different – lichens are symbiotic fungi and algae, and bryophytes are plants – they occupy similar habitats and are often studied together. They have been the focus of an increasing number of studies in the upper canopy (relative to vascular epiphytes), in northwestern North America (Rhoades, 1995; Peck and McCune, 1997; Sillett, 1995), the eastern deciduous forest of North America, the boreal forest of Canada, and the forests of the southern hemisphere (Diaz *et al.*, 2010; Wolf, 1994).

Bryophytes (phylum Bryophyta) are plants that lack true vascular tissues and organs. In canopy habitats they include

Table 1 Characteristics of vascular epiphytes

1. Reproduction	
A. Pollination	Exclusively zoophilous, flowers tend to be showy, pollinators highly mobile (Benzing, 1990, Chapter 5)
B. Breeding systems	Little studied, although many orchids appear to be allogamous (Benzing, 1990, Chapter 5)
C. Population structure	Little studied (ferns, Hooper and Haufler, 1997)
D. Seed dispersal	Most families endozoochorous, most species anemochorous (because of the dominance of Orchidaceae)
E. Life history	Almost all iteroparous, long-lived perennials
2. Vegetative	
A. Foliage	Usually evergreen, often succulent, and xeromorphic generally
B. Habit	Woody (wet forests) to herbaceous (wet and dry forests)
C. Shoot architecture	Various
D. Roots	Adventitious, specialized for holdfast, often reduced
E. Special features ^a	Impounding shoots (e.g., Bromeliaceae) and root masses (e.g., ferns), velamentous roots and absorptive foliar trichomes to prolong contact with precipitation and canopy washes, often lack capacity to grow in earth soil
3. Mineral nutrition	
A. Mycorrhizas	Possibly significant in Orchidaceae and Ericaceae, probably relatively unimportant elsewhere compared to terrestrial flora
B. Myrmecotrophy ^a	Nearly exclusive to epiphytes
C. Carnivory	Underrepresented in arboreal flora
D. Saprotrophy ^a	Phytotelm and trash-basket types
E. Special features ^a	Tolerance for low pH (wet forests), effective nutrient scavengers (dry forests), frequent reliance on organic substrates for nutrient ions
4. Photosynthesis/water balance	
A. Photosynthetic pathways	CAM overrepresented (tropical only) no typical C4 types, much interesting detail probably remains underdescribed
B. Water economy	Often very high
C. Moisture requirements	Various
D. Other ^a	Much flexibility, for example, facultative CAM, CAM-C4 intermediates

^aThese characteristics distinguish arboreal from terrestrial flora more than the others.

the mosses (with about 10,000 species worldwide) and leafy liverworts (leafy hepatics, 7200 species). Thallose (strap- or fan-shaped) liverworts and hornworts are usually restricted to moist, lower trunks. (Rhoades, 1995).

Lichens are important components of canopy biodiversity and of ecosystem processes (e.g., nutrient cycling, providing food for wildlife). Lichens are not a single taxonomically distinct category, but rather are symbiotic organisms, the association of a fungus (the mycobiont) and a photosynthetic partner (the photobiont), which are usually members of the Chlorophyta and Cyanobacteria. The degree of photobiont specificity varies among lichens. Generally, the mycobiont gives a lichen its overall form and provides the bulk of the biomass, outer protective layer, and a looser, inner layer that functions in physical absorption and storage of water and nutrients. The photobiont is usually restricted to the layer just below the protective covering of the mycobiont.

These cryptogams are poikilohydric, that is, they depend on an atmospheric supply of water and inorganic nutrients from precipitation, dew, or fog interception. In general, they absorb water rapidly and lack the water-resistant coverings or cuticles of vascular plants. Bryophyte growth forms have been described and discussed to understand their relationship to water use and conservation (Schofield, 1992; During, 1979). The gametophytes (vegetative bodies) of some species form tight cushions or spherical balls that expose a reduced surface area to retain water; others have a pendant, creeping habit that exposes them to maximal amounts of bark surface water. The sporophytes of many bryophytes are adapted to the

periodically xeric nature of epiphytic habitats and can distribute their spores over very wide ranges (Gradstein *et al.*, 1989).

Hemiepiphytes

Hemiepiphytes have been defined as plants that have, at some point in their lives, an “umbilical” connection to the ground. Whether roots or stems, these connections buffer hemiepiphytes from problems of water and nutrient supply that are faced by obligate epiphytes (Williams-Linera and Lawton, 1995). Hemiepiphytes begin their life cycle either as epiphytes and eventually send roots or shoots to the ground (primary hemiepiphytes) or as terrestrially established seedlings that secondarily become epiphytic by severing all connections with the ground (secondary hemiepiphytes) (Kress, 1986).

Hemiepiphytes exhibit a tremendous variety in growth form, impact on their hosts, and degree of dependence on hosts. They range from being erect and treelike in form to species that grow in scandent, clambering heaps. Their impacts on hosts range from lethal (e.g., strangler figs) to benign (e.g., shrubby Ericaceae in tropical cloud forests) (Williams-Linera and Lawton, 1995).

Parasites

The mistletoes, which are woody shrubby parasites, are an ecologically distinctive group of canopy-dwelling plants. They

have received a great deal of attention from botanists because of their ability to tap into the vascular system of their hosts, as well as from foresters, who have been concerned with reducing the damage they wreak through timber loss and mortality of desirable trees and shrubs, and also because they confer benefits, such as nesting habitats and food for birds. Parasitic mistletoes tend to show a greater tendency for host specificity than do the epiphytes (Calder and Bernhardt, 1983).

Canopy Plant Taxa Diversity

Vascular Epiphytes

Although the global species richness of plants is probably in the region of 270,000, neither their exact number nor their global diversity pattern is known. It has been estimated that possibly as many 24,000 vascular plant species are epiphytes (Kress, 1986), so they constitute a major part of the global biodiversity in the forest canopy.

Vascular epiphytes account for 10% of the total vascular plant diversity. Most extant epiphytes are angiosperms, representing about 9% of all angiosperm species (Table 2). Many vascular plant families (84) have adapted to life in the canopy, but relatively few taxa have radiated successfully. Within the angiosperms, approximately 31% of the monocots are epiphytic, whereas only 3% of the dicotyledons occupy the epiphytic niche. The Orchidaceae constitute approximately two-thirds of all epiphyte species (Kress, 1986). Other

important monocotyledon families are Bromeliaceae and Araceae. The important canopy-dwelling dicotyledon families are Cactaceae, Ericaceae, Gesneriaceae, Melastomataceae, Moraceae, Piperaceae, and Rubiaceae (Table 2; Kress, 1986). There are some large taxonomic groups of plants that contain no epiphytes or very few epiphyte species, for example, the Asteraceae, Leguminaceae, and Poaceae (Benzing, 1987). Less than 1% of the gymnosperms are known to be epiphytic. The Pteridophytes (ferns) are another important group of epiphytic plants, of which 29% are epiphytes (Kress, 1986).

The epiphyte quotient (proportion of an entire flora that is epiphytic) varies widely both geographically and among forest types. This ratio has been measured directly in only a few study sites (Table 3). Calculated epiphyte quotients based on published floristic studies in the Neotropics are known for Panama (12%), Peru (10%), Ecuador (22%), Costa Rica (26%), Venezuela (50%), and Florida (3%). In the Paleotropics, epiphyte quotients have been calculated from sites in Java (12%), West Malaysia (9%), Sri Lanka (4%), and Japan (0.5%). African forests seem to be much poorer in relative epiphyte species richness. In Ghana, a typical epiphyte quotient in forest plots is 8%; one direct measurement in central Africa (Rwanda and Zaire) was 3%.

It is generally regarded that the New World supports greater vascular plant diversity than the Old World. The number of vascular families containing at least one epiphyte species is very similar in the Paleotropics (43) and Neotropics (42). Within the Paleotropics, the representative families do not exhibit a homogeneous distribution. All 43 of the families occur in Australasia, but only 15 are found in Africa and

Table 2 Taxonomic distribution of vascular epiphytes

Major group	Taxonomic category	Number of taxa containing epiphytes in each category	Percentage of taxa containing epiphytes in each category

Madagascar. Vascular epiphytes are most diverse in the Neotropics, and less so in tropical Asia and Africa. There is approximately a twofold increase in species diversity in the Neotropics compared with Australasia, and a sixfold increase compared with Africa (Madison, 1977; Gentry and Dodson, 1987). Vascular epiphytes exhibit their greatest diversity in the montane cloud forests of Latin America. The temperate regions support considerably fewer species than tropical areas. Likewise, the temperate regions generally support more vascular epiphytes than do boreal areas.

Nonvascular Epiphytes

In general, bryophytes account for 9–10% of the total species diversity of the plant kingdom. However, no one has calculated how many species of nonvascular plants are obligate epiphytes, as “the idea of an obligate epiphyte is a slippery concept” (D. Griffin, personal communication). Rhoades (1995) has ably summarized the results of regional floristic studies (Table 4).

The standard growth forms of lichens are arbitrary, but have often been used to describe functional groups in canopy habitats. “Foliose” refers to leaflike, “fruticose” refers to thalli without distinctive dorsoventral arrangements, and “crustose” refers to thalli firmly cemented to a substrate. According to the International Code of Botanical Nomenclature, lichen species are given the name of their mycobiont; photobiont names are subsidiary. Morphology (sexual structures, asexual structures, and vegetative surface characters) and thallus chemistry are important species characters. Only a few studies have focused on the worldwide biogeography of bryophytes (Schofield, 1992) or lichens (Rhoades, 1995). For many inventories, the crustose lichens have been lacking or incomplete, which is unfortunate as they are the dominant cryptogamic form in outer canopies. The proportion of lichens that grow arboreally is unknown.

The bryophytes are a very old group of plants, perhaps dating as far back in the fossil record as the Devonian period when the first land plants are known to have existed. The combination of a long history and small airborne spores has allowed several bryophyte families to show wide geographic ranges. The tropical regions of Australia and Asia generally have more endemic genera of mosses, whereas in the Neotropics endemic liverwort genera are richer (Schofield, 1992). The cosmopolitan families are not restricted by latitude, but may show local altitudinal variation in some parts of their range. Representative moss families in the tropics include Bryaceae, Dicranaceae, Fissidentaceae, Funariaceae, and

Hypnaceae. Pantropical moss families include Calymperaceae, Pteroryaceae, Racopilaceae, and Rhizogoniaceae. Important temperate families are Aulacomniaceae, Encalyptaceae, Grimmiaceae, and Polytrichaceae. Representative tropical liverwort families include Frullaniaceae, Lejeuneaceae, Lophocoleaceae, Plagiochilaceae, and Radulaceae. Species-rich liverwort families in temperate regions are the Marsupellaceae and Scapaniaceae. All the species of hornworts are in a single family, Anthocerotaceae, which is most diverse in tropical ecosystems (Schofield, 1992).

Hemiepiphytes

The phylogenetic distribution of hemiepiphytes suggests that this habit has evolved independently a number of times (Putz and Mooney, 1991; Williams-Linera and Lawton, 1995). Twenty-five families and 59 genera contain hemiepiphytes (Table 5), with more than 820 species of primary hemiepiphytes and 650 species of secondary hemiepiphytes. These make up 1% of the total vascular plant species diversity, and 1% of the total canopy-dwelling vascular plant species. This is probably an underestimate, especially for woody hemiepiphytes (“lianas”), which are the most undercollected major canopy plant group. The stranglers most commonly occur in Moraceae and Clusiaceae, but are also found in Araliaceae, Rubiaceae, and Myrtaceae. The hemiepiphytic habit may have arisen from plants growing on rocks.

All of the hemiepiphytic monocotyledonous plants are secondary hemiepiphytes in the families Araceae and Cyclanthaceae. Secondary hemiepiphytes also occur in the dicotyledonous family Marcgraviaceae. Primary hemiepiphytes are represented by 20 families of dicotyledons. The majority of primary hemiepiphyte species are found in the families Araceae, Clusiaceae, and Moraceae. The Moraceae contain the most species of hemiepiphytes, with approximately 500 species in the genus *Ficus*. Primary hemiepiphytes (whose aerial roots eventually reach the ground) represent about 0.8% of all epiphytes with almost 2000 species (Gentry and Dodson, 1987).

As with vascular epiphytes, the contribution of hemiepiphytes to the diversity of the tropical forest canopy varies among forests. The percentage of trees colonized by hemiepiphytes has been reported for study sites in Venezuela (10% and 13%), Zimbabwe (13%), French Guiana (17%), and the Ivory Coast (21%). In neotropical lowland forests, stranglers and large hemiepiphytes can occur on 10–15% of the trees. Stranglers can occur in much higher densities in some

^cCategory includes liverwort.

^dEpiphytes identify mostly to genus.

neotropical palm savannas. A rich hemiepiphytic flora is typical of mountain forest and cloud forest sites, but wet lowland forest can also show high percentages of these species (25% in the case of La Selva Biological Station in lowland Costa Rica). In dry forests, hemiepiphytes are usually not present (Williams-Linera and Lawton, 1995).

Woody lianas are distinct features of tropical forests, rarely or never occurring in temperate forests. Lianas account for approximately 10% of the tropical flora worldwide. They occur in greatest density in Madagascar and Africa, and less so in neotropical and Australian forests. At some sites in Madagascar, an average of 122 lianas with >2.5 cm dbh per 0.1 ha is reported, whereas lianas average only five individuals per 0.1 ha in northern temperate forests.

Lianas are more abundant in south temperate forests than in north temperate forests. The important families in north temperate forests are Anacardiaceae, Araliaceae, and Vitaceae. South temperate forests support more than twice as many families. Families such as the Bignoniaceae, Gesneriaceae, Gramineae, Lardizabalaceae, Saxifragaceae, and Vitaceae account for the majority of the climbing species (Putz and Mooney, 1991).

Parasites

About 1400 species of mistletoe occur in forests, woodlands, and shrublands on every continent except Antarctica, with most species in the tropics. Less than 1% of the total vascular plant species are mistletoes, and this group accounts for less than 1% of the total canopy-dwelling vascular plant species.

Mistletoes occur in two plant families. The Loranthaceae contain approximately 900 species in 65 genera, and the Viscaceae contain 400 species in 7 genera. The most species-rich genera in the Viscaceae are *Phoradendron* (170) and *Viscum* (100). The Viscaceae contain four genera restricted to the Old World, two genera that occur only in the New World, and one predominately New World genus is also widespread through Eurasia and Africa. In the Viscaceae, the New World genera *Dendrophthora* and *Phoradendron* contain about half of the 397 species of the family.

Diversity of Habitats of Canopy Plants

Canopy Microclimate

The values of light intensity and quality, temperature, wind, moisture content, and concentrations of various gases and aerosols are strongly modified by canopy structure in several ways. Canopy surfaces act as passive bodies for the absorption of wind energy, the dissipation of turbulence, and the sorption of heat and radiation. They also actively participate in exchanges of biologically important compounds, such as CO₂ and water vapor, which in turn may have an impact on regional, and even global, climate. Canopies also act as “filters” that remove small-scale turbulence, but allow large eddies to penetrate (Parker, 1995). Canopy structure therefore has a direct effect on the climate surrounding individual leaves, on the modification of microclimate through the layers of the forest, and on the large-scale environment of forest regions (Ambrose, 2004; Cardelus and Chazdon, 2005).

^aModified from Williams-Linera G and Lawton RO (1995) The ecology of hemiepiphytes in forest canopies. In: Lowman MD and Nadkarni NM (eds.) *Forest Canopies*, pp. 255–283. San Diego, CA: Academic Press.

^bFrom Putz F and Mooney HA (1991) *The Biology of Vines*. Cambridge, UK: Cambridge University Press.

Canopy conditions are generally typified by more intense sunlight, greater extremes of relative humidity, higher water stress, and a smaller, more pulse-supplied pool of nutrients than on the forest floor. Sunlight attenuation can be as great as 98% between the tops of emergent trees and the levels reaching the forest floor. Rates of evaporation in the canopy have been recorded that are comparable to those occurring in open savannas. Relative humidity can range from nearly 100% at night to less than 30% during midday in the dry season. Differences in canopy versus forest floor wind speeds can also be extreme, especially in tropical cloud forests. In one Costa Rican ridge cloud forest, wind speeds within the canopy (10 m) were clocked at 11.3 m s^{-1} , while forest floor (2 m) speeds were only 4.0 m s^{-1} (Williams-Linera and Lawton, 1995).

Spatial Scales of Canopy Plant Diversity

The forest canopy is a three-dimensional subsystem of the forest itself. Canopy plants need relatively little space in order to develop a striking diversity. In an Ecuadorian montane forest, for example, 109 epiphyte species occurred on just 20 m^2 of branch surface, compared to only 67 terrestrial plant

species on a 100-m² ground plot of elongated shape in the immediate vicinity of the phorophyte. The amazing concentration of epiphytes on single trees has often attracted the attention of naturalists. For example, 66 epiphyte species were found on one specimen of *Decussocarpus rospigliosii* in the Carbonera Forest in Venezuela.

The canopy offers its occupants a wide variation in water, light, and nutrient regimes compared to the understory and the forest floor, and this variety undoubtedly contributes to arboreal plant diversity. For example, soil-like deposits and litter in the canopy function as a medium for canopy-dwelling plants that have well-developed root systems, such as vascular epiphytic shrubs. This material has a high organic content and is derived principally from leaf litter, feces, and other faunal remains. Also present is a small mineral component derived from fine particles carried there by wind, fog, and rain.

In tropical America, epiphytic bromeliads increase the volume of arboreal soil and litter by creating water-filled tanks ("phytotelmata") in which litter accumulates and soil forms. Although these arboreal epiphytes and their associated soils are patchily distributed, they are linked by climbing vegetation, by percolating rainwater, and probably by the movement of animals, and so they can be likened to a three-dimensional matrix of interconnected islands.

Within a forest, microsite differences exist at many different spatial scales: within a single branch; between branches at different heights of the tree; between trees of different architecture; and within stands of differing topography and aspects. Some studies have described variation in the distribution of canopy plants within single crowns. In a West African rain forest, for example, more than 75% of the orchid species grow on the inner branches, 48% in a middle zone, and only 4% in the outer canopy. Some research has linked differences in microsite water regimes and levels of sunlight input to differential distribution of certain canopy plants between outer and inner crowns; other arboreal species display a "generalize distribution."

Host Tree Specificity

Studies of the mechanisms influencing host tree specificity are scant. It has been suggested that bark texture and pH influence patterns of colonization. For example, the orchid *Cymbidiella pardalina* obligately grows exclusively on the fern *Platynerium madagascarense*, whereas other epiphytes are found on numerous host tree species. This phenomenon warrants further investigation.

Diversity of Growth Habits in Canopy Plants

Canopy-dwelling plants exhibit a great diversity of ecological adaptations, which is most likely a result of their diverse phylogenetic origins and the possibilities for adaptive specialization in the canopy habitat. The one unifying feature of these mechanically dependent plants is their occurrence in the canopy (Benzing, 1987). For vascular epiphytes, the different "habits" can be classified by several criteria, including degree of dependence (obligate vs. facultative),

nutritional dependence (parasitic vs. commensalistic), degree of light demand (heliophiles vs. sciophytes), architecture (tank vs. atmospheric), substratum (e.g., ant-gardens, humiphiles), or carbon fixation pathway (Crassulacean acid metabolism (CAM) vs. C₃) (Benzing, 1990). Similarly, the great diversity of habits within the hemiepiphytic species ranges from stranglers, which ultimately become freestanding trees, to epiphytes that have only one root connecting with the ground.

Diversity of Physiology

The C₃ photosynthetic pathway is more typical of epiphytes inhabiting the canopies of cloud forests and cool, shaded, humid microsites. Forest canopies with more arid conditions favor CAM plants. The occurrence of a C₄ epiphyte has not been documented. Some families containing C₄ plants such as Asteraceae, Cyperaceae, Orchidaceae, and Poaceae also contain epiphytic species, but none is known to exhibit C₄ photosynthesis.

Diversity of Modes of Resource Acquisition and Retention

Nutrient acquisition in canopy plants occurs through many modes, including rainwater, bark and leaf leachate, nitrogen-fixing cyanobacteria, airborne particles, carton nests, crown humus, and decomposition of the host.

Humus Epiphytes

Ecologically, humiphily is the most common form of nutrient acquisition and supports the greatest diversity of epiphytes. An overwhelming majority of families containing at least one epiphytic species have at least one humiphile species, and most families contain only humiphile species (Benzing, 1987). Humus-rooted epiphytes include Ericaceae, Gesneriaceae, Melastomataceae, Piperaceae, and Rubiaceae, as well as the hemiepiphytes in Moraceae and Araliaceae. Many of the humus epiphytes are facultative. The obligate species exhibit a diversity of xeromorphic adaptations, including leaf succulence, a flattened pendulous growth form, and poorly developed root systems with strong mycorrhizal associations.

Tank and "Trash-Basket" Epiphytes

Some bromeliads, ferns, and orchids collect water, airborne particles, and leaf litter in the rosette created by overlapping fronds or leaves. Ferns in the genus *Asplenium*, for example, have roots that grow in the form of a trash basket to gain access to nutrients.

Ant-Associated Epiphytes

Myrmecophily is a common feature of vascular epiphytes and may be strictly a canopy phenomenon. Nest garden species include Araceae, Bromeliaceae, Cactaceae, Gesneriaceae, Marcgraviaceae, Orchidaceae, Piperaceae, and Rubiaceae. In Australia, Asclepiadaceae, Melastomataceae, and Rubiaceae occur in less-studied ant-garden symbioses. Asclepiadaceae, Bromeliaceae, Melastomataceae, Orchidaceae, Polypodiaceae, and Rubiaceae contain specialized ant-garden species. Rubiaceae appear to be the most specialized ant-garden species.

Some ferns and orchids have hollow rhizomes (Polypodiaceae), hollow tubers (*Solanopteris* spp.), and hollow pseudobulbs (*Schomburgkia* and *Laelia*) that provide domatia for ants.

Bark Epiphytes

To inhabit the bark substrate, epiphytic plants must cope with very low levels of water and nutrient availability. Therefore, many of the bark epiphytes are obligate epiphytes, including many specialized orchids.

Atmospheric Epiphytes

Some bromeliads (e.g., *Tillandsia*) have special hairs (trichomes) that allow them to absorb water from the atmosphere over the entire surface of their leaves.

Canopy Plant Biodiversity and Conservation Biology

General Considerations of Canopy Plant Conservation

Because of their small size, high degree of endemism, and frequent microsite specificity, epiphytes may be more vulnerable to human-induced disturbance than terrestrial plants. Methods to conserve existing epiphyte populations and floras have been discussed (e.g., Lowman and Nadkarni, 1995). Studies have shown the value of older trees in forests as habitats for certain sensitive species.

Effects of Forest Fragmentation and Habitat Conversion

The effects of forest fragmentation and habitat conversion on canopy plant diversity are poorly documented, especially in the tropics. It is generally accepted by researchers that secondary bryophyte and lichen communities are very different from those in primary forests (Gradstein *et al.*, 1989). Most studies indicate a decrease in species richness between secondary habitats and primary forests, and even disturbances at small spatial scales (within a branch) are reported to result in a decrease in diversity.

Shade epiphytes growing in the understory are more affected by habitat conversion than the sun epiphytes of the canopy, but not all sun epiphytes are able to recolonize following disturbance. The available data from investigations of the regeneration rates of temperate and subtropical canopy plants indicate that many species are slow to recover. The rates for bryophytes range from 25 years in Australia to 80–100 years in California. In Britain, it is estimated that lichens may require 500 years to successfully regenerate.

Effects of Global Environmental Change

Water stress is a major limiting factor for plants inhabiting the crowns of trees. A rise in global temperatures may have an impact locally on the relative humidity of some forest canopies. Experimental work along an altitudinal gradient indicates that the species composition of canopy plant communities may be altered by such changes in temperature and humidity (Nadkarni and Solano, 2002).

Vulnerability of Canopy Plants to Extinction and Invasion

With one exception (an orchid, Sosa and Platas, 1998), there are no records of a specific canopy plant extinction in modern times. However, numerous endemic species are endangered or threatened by habitat conversion (Gradstein *et al.*, 1989). A great deal of information indicating that lichens are very susceptible to air pollution and metal ion deposition has accumulated over the past several decades (Rhoades, 1995). Gradstein *et al.* (1989) suggest that relatively small reserves containing a diversity of life zones should suffice to conserve cryptogam biodiversity if the reserve is large enough to maintain a viable population of host trees. However, they warn that these recommendations are based on very preliminary data and more inventory data and taxonomic work are needed to better define species ranges and to determine which species are locally rare or endemic. Mistletoes are generally very susceptible to environmental changes (Calder and Bernhardt, 1983).

Areas for Further Study

General Considerations

Habitat loss and climate change are growing threats to plant communities. Arboreal plants provide many opportunities and challenges for biologists from many disciplines, and because these plants have no access or sporadic access to terrestrial soil, they make excellent experimental subjects to study physiology and stress. Canopy plants warrant attention for the roles they play in forest dynamics, which affect biodiversity, productivity, and nutrient cycling. A list of research questions was created for vascular epiphytes (Table 6); these questions can also be related to the study of other types of canopy plants.

Monographs and Inventories

There is a pressing need for extensive and intensive work on plants that live in the canopy. However, the lack of resident plant taxonomists is a serious concern. There are many more taxonomists in the more developed countries where the resources and infrastructure exist to train students, but there are relatively few specialists in less developed countries where many of the biological resources exist.

However, efforts to create monographs and inventories of canopy-dwelling plants have been increasing. For example, botanists at the Missouri Botanical Gardens and their collaborators have compiled inventories of regional floras. To date, Peru, Panama, Venezuela, and the Guianas have received a great deal of attention, and the study of other floras (e.g., Colombia and Chile) is increasing. To fully represent regional biodiversity, it is crucial that botanists collect plants in the canopy. Likewise, to fully understand global biodiversity, the generally undercollected groups must be collected in the canopy (e.g., lianas and cryptogams). In terms of cryptogams, work needs to continue on broad regional inventories of all tropical species and of crustose lichens worldwide. The bryoflora of Australia is particularly poorly known.

Table 6 Research questions and opportunities for canopy plants

<i>Subject</i>	<i>Obvious</i>	<i>Questions remaining</i>
1. Fidelity to canopy versus other substrates	Occurrence on trees ranges from accidental to obligate.	What factors differentiate canopy from terrestrial substrates for the obligate epiphyte? How has specialization for arboreal life compromised capacity to survive on the ground?
2. Requirements for specific types of arboreal substrates	Specific epiphytes typically colonize only subsets of the many types of substrates present in occupied tree crowns.	What plant characteristics determine microsite requirements for twig, bark, humus, ant-nest garden, etc., epiphytes?
3. Plant adjustments to the often transitory and relatively unpredictable supplies of moisture in forest canopies	Broadly occurring accommodations to drought (e.g., CAM, xeromorphy) are particularly well developed among the epiphytes.	What is the nature of the moisture supply in forest canopies and how are mechanisms such as photosynthetic pathways, osmotic balance, and stomatal behavior fine-tuned to reduce risk and maximize effective use of available moisture?
4. Plant adjustments to the absence of mineral soil	A variety of organic substrates, including the products of mutualistic biota, serve in lieu of earth soil as sources of nutritive ions.	How is impounded litter processed for phytotelm epiphytes? How substantially do ant mutualists contribute to the nutrient budgets of associated epiphytes? How are the more oligotrophic epiphytes (e.g., atmospheric bromeliads) equipped to scavenge scarce ions and use them economically?
5. Impacts of arboreal ants	Some epiphytes require ants for dispersal and to provide rooting media.	How much arboreal flora beyond the obvious ant-nest garden and myrmecotrophic species are dependent on ants for dispersal, substrates, and defense?
6. Epiphytic vegetation as a resource for canopy fauna	Much arboreal fauna, particularly invertebrates, use epiphytes as resources.	What is the full extent of this dependence and what are the broader consequences of these dependencies for the forest community?
7. Epiphyte involvements in nutrient cycles	Nutritional piracy exists. Epiphyte biomass sometimes contains much of the nutrient capital present in a forest ecosystem.	To what degree and under what conditions does the presence of an epiphyte load have an impact on the nutritional status of a phorophyte?
8. Impacts on community productivity and patterns of resource use	Resources present in canopy soil (e.g., N and P) at least sometimes yield photosynthetic returns at different rates than those of supporting soil-rooted vegetation.	How does the presence of substantial canopy soil affect aggregate forest productivity and help determine overall resource-use efficiency?
9. Conservation	Because many epiphytes occupy narrow ranges (especially orchids), often in regions of rapid development, endangered status is correspondingly common.	What conservation strategies are likely to preserve the greatest diversity of epiphytes?
10. Indicators of habitat quality and global change	Some epiphytes possess characteristics that impart extraordinary utility as air quality monitors.	How can epiphytic vegetation be more effectively used to monitor changing conditions in the troposphere?
11. Succession	Presumed serai stages identified.	Do species displace one another on bark? If so, by what mechanisms?
12. Community organization	Species often co-occur in predictable assemblages, but often distribution and spacing among individuals are random.	Are the factors responsible for the distributions and combinations of species on bark primarily density dependent or density independent?

Herbaria and Databases

Certain herbaria have significant canopy plant collections (Madison, 1977; Kress, 1986). Herbarium studies have been conducted at the Harvard University Herbaria, the Marie Selby Botanical Gardens, the Huntington Botanical Gardens, the Herbario Nacional Colombiano, the State University of Utrecht herbarium, and the University of Florida.

Several major botanical gardens have produced useful databases. For example, The Missouri Botanical Gardens has developed an on-line database (TROPICOS) for the floras of several Neotropical countries. Such databases can be of great use to systematic biologists and conservationists by providing the most up-to-date information available. With the increasing attention being paid to canopy plant ecology (e.g., Lowman and Nadkarni, 1995), perhaps it is time to initiate a canopy plant biodiversity database.

Experimental Fieldwork

Experimental field studies to investigate the potential effects of forest harvesting on plant community composition and species richness should be conducted, especially in tropical regions, so as to include biodiversity objectives in forest management practices. Humus epiphyte communities growing in bryophyte mats, for example, are ideal for experimental fieldwork because entire moss mat communities are easily transplanted with minimal disturbance to the rooting medium. Transplanting epiphytes along an altitudinal gradient is useful in helping to predict the effects of environmental change. The experimental removal of epiphytic mats is also useful in monitoring epiphyte succession and recolonization.

Ethnobotany of Canopy Plants

Ethnobotanical knowledge and usage of canopy plants is widespread in cultures around the world (Lowman and Nadkarni, 1995). However, the pharmaceutical potential of canopy plants has only begun to be investigated. In particular, the bryophytes and lichens have not been rigorously explored in this regard. The potential importance of canopy plants for human use may spark resources needed to learn more about both applied and basic aspects of these diverse organisms.

Conclusions

Due to the extremely high diversity of epiphytes, as well as the relatively unknown nature of their response to disturbance and resilience at all spatial scales, canopy plants constitute an entity that requires the highest level of awareness for good stewardship and conservation. Although many epiphytic taxa and their environments are clearly healthy and vibrant, others may be vulnerable to changes in conditions wrought by human causes: deforestation, forest fragmentation, pollution, and climate change. Attention should be paid to the maintenance of epiphyte biodiversity and the ecosystem services they provide not only in primary forests, but also in secondary forests, pasture relict trees, and plantations. Such areas are especially critical in tropical regions and in temperate

rainforests where land areas of primary forests are now dwindling and in decline.

Acknowledgments

This summary of canopy plant diversity was supported by the National Science Foundation. The authors thank the Monteverde Cloud Forest Reserve and the Tropical Science Center in San José, Costa Rica for maintaining and protecting the Research Area. Funds were provided by Evergreen State College Faculty Sponsored Research, the National Science Foundation (Ecology Program (BSR 86-14935, 89-18006, and DEB-0956301), Long-Term Studies Program (DEB 96-15341), Database Activities Program (BIR 96-30316)), the Whitehall Foundation, the National Geographic Society, and the Evergreen Foundation. Many plant taxonomists provided information on epiphyte floristics. The authors thank A. S. Taylor (Zamiaceae), T. Croat (Araceae), R. Faden (Commelinaceae), H. Luther and B. Hoist (Bromeliaceae), H. Kenedy (Marantaceae), L. Thein (Winteraceae), P. Berry and P. Hoch (Onagraceae), P. Lowry and D. Frodin (Araliaceae), M. Endress (Apocynaceae), and W. J. Kress (for many families). Camila Tejos and Dennis Aubrey provided critical help in updating an earlier version of this article.

Glossary

Disturbance An event that results in a radical change in environment, usually as a consequence of death of the dominant plants.

Food web A set of species that live together and a specification of which species “eat” which other species.

Forest stand A relatively homogeneous forest landscape unit that can be distinguished from neighboring units by forest age or composition.

Forest structure The arrangement of all the parts of the forest stand – stems, branches, leaves, roots, and so on.

Keystone species A species that performs some crucial activity in the ecosystem and for which there is little or no redundancy.

Succession Sequential change in the relative dominance of various species in the biotic community at a location.

Introduction

Forests occur naturally wherever environmental factors permit the upright woody growth form of trees to be a successful strategy. The primary advantage that trees realize in such settings is the ability to gain a competitive edge over any smaller neighbors in gaining access to solar radiation for photosynthesis. Thus, forests dominate the natural landscape in all regions except where the upright woody growth form is not possible or where other mitigating environmental factors eliminate any competitive advantage of being tall. For example, in the Great Plains of North America grass fires were usually too frequent to allow trees to become established and outcompete the grasses for sunlight.

Ecologists have classified the forests and other vegetation of the world into biological regions, or biomes, on the basis of the physiognomy (outward form) and species composition of the dominant plants. The biome classification represents ecological patterns at a very large scale. However, the patterns that ecologists endeavor to explain occur at a wide range of spatial scales, from global to local. Global scale maps of the world's biomes have been constructed to illustrate the broad distributional patterns of the biota. Ecological patterns at smaller scales are represented by subdividing the various biomes to provide more detailed classifications and maps. In essence, the forest ecologist regards the global ecosystem as consisting of a nested series of ecological associations, at smaller and smaller spatial scales, down to the level of the relatively uniform forest stand.

The focus of ecological classification systems on the dominant plants is not just a convenience; the dominant plants in terrestrial ecosystems (e.g., the trees in the forest) play a crucial role in setting the stage for all the other organisms because they convert solar energy into food for the food web and they form the three-dimensional structure that constitutes the habitat of most associated biota. Hence, it is of primary importance in studying the ecology of forests to understand what controls the distribution and abundance of trees. However, this is not to say that the other organisms are not important to the functioning of the ecosystem; in fact, many of the less prominent organisms play important roles in regulating the distribution and abundance of the trees.

Underlying these ecological classification systems and maps at the broad scale is the principle that climate is the environmental feature that exerts primary control over the distribution of organisms on the earth's surface. This principle was realized long ago by European geographers who observed during their explorations the coincidence between the broad patterns of climate and vegetation physiognomy on earth. The key components of climate, temperature and precipitation, exert this control through their effects on the growth of plants. Different plant traits, expressed in part as whole plant physiognomy, prove to be most suitable for growth and survival under different combinations of temperature and precipitation. Hence, climatic patterns largely coincide at the broad scale with the patterns of distribution of forest biomes. Expressed most simply, the effect of climate on vegetation distribution can be plotted in terms of mean annual temperature and precipitation (**Figure 1**); forest vegetation is restricted to relatively moist climates. However, annual averages cannot account for the important effects of climatic seasonality – variations in temperature and precipitation through the year – in determining biome distributions. More complicated systems of expressing the influence of climate account for the important effects of seasonal drought and of subfreezing temperatures on plant growth and activity.

The principle that climate exerts primary control over the distribution of organisms fails to account for the observation that some equivalent climates support vegetation with differing composition and physiognomy. For example, the temperate rain forests of the Pacific Northwest of North America are dominated by evergreen needleleaf trees whereas in some equivalent climates of the southern hemisphere (New Zealand and South America) evergreen broadleaf forests may dominate. These differences reflect the fact that the flora and fauna that have developed by biological evolution in the various regions of the world are quite distinct because they have been geographically isolated from one another. Several biogeographic zones have been identified by botanists and zoologists, and these zones reflect geologic history, especially continental drift. For example, plant geographers typically recognize four plant domains whose floras are distinct from one another: (1) paleotropical (Old World Tropics),

Figure 1 The effects of mean annual precipitation and temperature on vegetation. Whittaker (1975).

(2) neotropical (New World Tropics), (3) north temperate, and (4) south temperate. To expand on our earlier principle, then, climate together with the available flora and fauna exert primary control over the distribution and abundance of organisms on earth. This principle points toward the likelihood that human effects on climate and the introduction of exotic species across the globe will have profound consequences for ecology and biodiversity.

At a more localized scale, species distribution and abundance are also affected by secondary environmental factors, topography and soils. Topography exerts its influence in part by locally modifying climate; for example, in the northern hemisphere south-facing slopes are warmer and drier than north-facing slopes. Also, topography influences the environment through the action of gravity moving matter downhill (e.g., water, soil particles). Soil supplies the essential environmental resources, water and mineral nutrients, for tree growth. Soil properties reflect the combined effects of geologic, climatic, and biologic forces, emphasizing the complex web of cause and effect that underlies ecological patterns and processes.

Geologists have divided the earth's landscape into physiographic provinces that reflect the effects of geological processes on the earth's surface features. Within each physiographic province, relatively orderly and recurring patterns of topography and soils are observed that differ fundamentally from those of neighboring provinces. For example, in the coastal plain province of the eastern United States, sandy sediments have emerged from the receding ocean to leave a gently rolling landscape of porous, sandy soils. Forest patterns reflect subtle variations in topography and drainage. In contrast, directly to the west, the ridge-and-valley province is marked by recurring combinations of bold narrow ridges of

resistant rocks and intervening valleys underlain by softer substrates like limestone and shale. The forest patterns in this province directly mirror the striking gradients in environment that result from the combination of topography and soils determined by the bedrock geology of the province. An understanding of the ecology of these two regions begins with the recognition of the underlying differences in geological forces that have shaped their physiography.

One additional factor that strongly regulates the composition of the biotic community is the legacy of disturbance events. Disturbance is a natural phenomenon in all ecosystems and is defined as any event that results in a change in environmental conditions and resource availability, usually as a consequence of death of the dominant plants. Among the most prominent natural disturbance agents in forest ecosystems are fire, windstorms, and irruptions of pests and pathogens. When disturbances occur at a spatial scale that is much larger than the area occupied by individual dominant plants (i.e., large-scale disturbances), they so profoundly alter the environment that the suite of plants that subsequently colonizes the disturbed site may be quite different from the original community. These large-scale disturbances initiate the ecological process of succession – that is, successive changes in the composition of the biotic community occur as a result of progressive changes in environmental factors. Hence, the actual composition of the biotic community at any particular time and place depends not only on climate, flora and fauna, topography and soils, but also on the time interval since the last large-scale disturbance that initiated successional change – as well as the nature and intensity of that disturbance event. That disturbance has played a major role in shaping ecological patterns and processes is evident from the many traits of the flora and fauna that reflect the selective force associated with disturbance.

The natural disturbance regime that characterizes any particular ecosystem depends on exogenous factors that act as disturbance agents (e.g., the combination of drought, lightning, and wind that favors the occurrence of fire; or frequent exposure to hurricanes or tornadoes in certain geographic regions) as well as endogenous factors, such as the traits of the plants themselves, that influence the frequency or intensity of the disturbance. For example, pine forests are more prone to fire disturbance than deciduous broadleaf forests in part because the fuels produced by pine trees are more flammable. And forests on sandy soils are more prone to fire because coarse soils dry out more rapidly than fine-textured soils. Thus, the influences of disturbances, environment, and biota may be mutually reinforcing in shaping ecological patterns and processes.

The prevalence of disturbance and succession in natural forest ecosystems complicates the task of classifying and mapping forest distributions, particularly at smaller scales, because forest composition is continually changing. Recognizing this problem, ecologists have defined the climax forest association as the assemblage of species that would persist under any particular combination of environmental factors in the absence of large-scale disturbance. In many regions, however, the recurrence of large-scale disturbances is naturally so frequent that climax forest associations rarely develop, and the practical value of such a strict climax concept is somewhat

limited. However, in some regions where large-scale disturbances are infrequent, particularly under humid climates (where fires are rare) and areas not often exposed to intensive windstorms (i.e., the humid tropics and some temperate areas), climax forest associations probably were common prior to the advent of anthropogenic influences. Natural disturbance regimes in these forests consisted of small-scale events resulting from the death of individuals or small groups of trees in a patchwork mosaic. Although the composition and structure of various patches would differ, at a larger scale the average composition of the forest ecosystem would remain relatively steady (i.e., it would exhibit a shifting-mosaic steady-state). These observations illustrate the importance of the scale of observation to our understanding of ecological patterns and processes.

Biodiversity in Forest Ecosystems

General Patterns

The number of species observed in any particular forest varies markedly across the earth's forest biomes. Biodiversity can be conceived as consisting of three distinct elements, termed the gamma, alpha, and beta diversity. The total diversity in a large area, the gamma diversity, can be partitioned into two components, the local (alpha) diversity in a single habitat or forest stand, and the turnover of species between stands, the beta diversity. High gamma diversity could be associated either with high alpha diversity, high beta diversity, or both. Ideally, considerations of the patterns of biodiversity across forest regions need to account for the contributions of these different elements of biodiversity. Unfortunately, studies of forest biodiversity patterns generally have not provided samples of sufficient detail to resolve these elements, and more systematic approaches are needed. Nevertheless, many valuable insights into the patterns and causes of biodiversity variation across forest regions have emerged from research to date.

The most striking pattern of forest biodiversity is the latitudinal gradient: Much higher biodiversity is observed both locally and regionally in tropical than in temperate forests. Because observations are most comprehensive for tree species, the following description focuses on these taxa.

The general relationship between latitude and the alpha diversity of trees is illustrated by a plot of the number of species in 0.1-ha samples taken from around the world (Figure 2). At one extreme are lowland tropical rain forests in the upper Amazon basin where on average every second tree in a sample belongs to a different species; at the other extreme, a variety of natural, mono-specific forests are common in many temperate and boreal regions. Within the tropical region considerable variation in alpha diversity has been observed (Figure 2). The two most prominent features correlated with this variation are annual precipitation and biogeographic province or region. For example, the average alpha diversity (number of tree species in 0.1-ha samples) of neotropical lowland wet and moist forests is 152 species, whereas for seasonally dry forests the average is 65. And the alpha diversity of trees in Africa is generally much lower than for eastern Asia and America (Figure 3). The

Figure 2 Species richness of 0.1-ha samples of lowland (<0.1000 m) forest as a function of latitude. Dashed line separates dry forest (bottom) from moist and wet forest (top) with intermediate sites (moist forest physiognomy despite relatively strong dry season) indicated by alternate lines. In: Bullock SH, Mooney HA, and Medina E (eds.) *Seasonally Dry Tropical Forests*, pp. 146–194. Cambridge, England: Cambridge University Press.

extremely high alpha diversity of lowland tropical rain forest is not paired with equally high beta diversity. For example, the 307 tree species identified on a single 1-ha plot in the Ecuadorian Amazon constituted about 16% of the total tree flora (trees ≥ 5 cm diameter) of Amazonian Ecuador and a single 50-ha plot at Pasoh, Malaysia contained 830 species, 20–30% of the total tree flora of this country.

By comparison, tree species diversity in the temperate latitudes is much lower: The enormous area of temperate zone forests harbors only 1166 tree species, not much more than the 50-ha plot at Pasoh! As for the tropics, however, striking geographic differences in the diversity of tree taxa are observed in the temperate zone. The highest gamma diversity is in east-central Asia, with intermediate levels in eastern North America and lowest in Europe (Table 1).

A comprehensive explanation of these global patterns in tree species diversity remains elusive, but a growing consensus on the role of historical or biogeographic factors and local physical habitat factors is emerging. The overall lower diversity of temperate than tropical regions probably is explained in part by the physiological constraints on colonization imposed by the need to tolerate subfreezing conditions and by the smaller contiguous area in temperate regions. Regional differences between biogeographic provinces in the temperate zone appear to owe in large part to higher extinction rates in Europe and North America during the Pleistocene glacial epochs as well as greater access of the east Asian region to dispersal routes from the tropics. Similarly, the combination of geographic area and climatic differences probably explains the contrasts in diversity between tropical Africa versus America and east Asia and between wet and dry forests. As noted by Latham and Ricklefs (1993), “further resolution of the causes of diversity patterns will require new paleontological, biogeographical and taxonomic data and synthesis” (p. 310).

Forest Structure and Pattern and Disturbance Regimes

The local biodiversity in particular forests depends on the complex suite of factors that characterize the habitats of individual species. These factors include such components as the species composition, phenological timing, structural complexity, and horizontal patterning of the vegetation, which

in turn depend on environment and the legacy of disturbances. The dominant plants (i.e., trees in forests) play a pivotal role in defining the habitats for associated organisms by providing food and shelter and by regulating the local microenvironment. For some organisms (e.g., many insects) host-specific interactions with particular dominant plants result in strong correlations in their distributions, so that forest composition is the key factor influencing the composition of associated species. For other organisms, the structural and horizontal patterning of the dominant vegetation may be more important than composition alone.

The importance of the three-dimensional spatial arrangement of the branches and leaves of the plants in defining animal habitats was realized by pioneers in the study of ecology and evolution. MacArthur and MacArthur (1961) demonstrated that the diversity of birds in forests of the eastern United States could be predicted by the structural complexity of the vegetation (Figure 4): in habitats with high foliage-height diversity (FHD; defined by the formula $FHD = \sum p_i \ln p_i$ where p_i is the proportion of total foliage area in the i th layer), bird diversity was much higher than in habitats with low FHD. Moreover, this relationship largely transcended differences in plant species diversity. Similarly, for ground-dwelling organisms, the complexity of habitat at the soil surface – including vegetation cover, litter, rocks, fallen logs, and moisture – is strongly correlated with local biodiversity. By extension the below-ground structural complexity might influence diversity of subterranean organisms, but little work on this topic has been accomplished.

The horizontal pattern of forest vegetation, particularly the arrangement of relatively uniform forest stand units across the landscape, influences biodiversity of the region and is the subject of a newly emerging branch of ecology – landscape ecology. The edges or ecotones (zones of rapid change in plant species composition) between forest stand units or forest associations often provide qualitatively different habitat than the interiors of those units; hence, the size, shape, and spatial arrangement of forest stands in the landscape influence the populations of associated species. Edges and sharp ecotones between stands may arise because of environmental discontinuities (e.g., topographic depressions where soil water accumulates) or because of the legacy of past disturbances. Thus, the local biodiversity of forests reflects both the compositional and structural diversity of the plants as well as the arrangement of units of relatively uniform composition and structure that we define as forest stands.

The structure of any particular forest stand traditionally has been defined as the distribution among age or size classes of the trees in a forest stand. Even-aged stands arise as the result of large-scale disturbances in which all or most of the large trees in an area are killed by a natural disturbance agent (e.g., crown fire, hurricane, fungal pathogen) or by human activity. The forest that arises on such a site consists of trees of roughly the same age, from new seedlings that colonize the site or from advanced regeneration (preexisting seedlings and saplings that escaped the disturbance). The process of stand development following large-scale disturbance results in gradual changes in the structure of the forest, as the growth, mortality, and recruitment of new individuals proceeds. These changes in forest structure include not only age structure, but also the

Table 1 Summary by taxonomic level and region of moist temperate forest trees in the Northern Hemisphere

Taxonomic level	Number of tree taxa characteristic of moist temperate forests in:				
	Northern, central, and eastern Europe	East-central Asia	Pacific slope of North America	Eastern North America	Northern Hemisphere (total)
Subclasses	5	9	6	9	10
Orders	16	37	14	26	39
Families	21	67	19	46	74
Genera	43	177	37	90	213
Species	124	729	68	253	1,166
Families excluding those of predominantly tropical	18	37	18	29	41
Distribution (% of total)	(86%)	(55%)	(95%)	(63%)	(55%)
Genera excluding those of predominantly tropical	41	121	35	77	149
Distribution (% of total)	(95%)	(68%)	(95%)	(86%)	(70%)
Species exclusive of predominantly tropical genera	122	570	66	236	987
(% of total)	(98%)	(78%)	(97%)	(93%)	(85%)

Figure 4 Relationship between foliage height and bird species diversity in areas of eastern North American deciduous forest. Modified from MacArthur RH and MacArthur JW (1961) On bird species diversity. *Ecology* 42: 594–598.

spatial arrangement of the stems, branches, foliage, and roots of the plants that define the habitat of other biota in the forest. Moreover, changes in species composition of the forest usually accompany stand development, as species capable of growing in the shaded understory replace the pioneer species that colonize the disturbed site.

A typical sequence of forest stand development following large-scale disturbance has been characterized by [Oliver and](#)

[Larson \(1990\)](#) as consisting of four stages: (stage 1) stand initiation, (stage 2) stem exclusion, (stage 3) understory reinitiation, and (stage 4) old growth. In the stand initiation stage, trees colonize the disturbed area. The time interval of this stage varies markedly depending on the severity of the disturbance, environmental factors at the site (e.g., climate and soils), and often herbivory. This stage concludes when the forest canopy becomes closed or when some soil resource (often water) becomes limiting to further increases in the leaf area of the forest. During the stem exclusion stage resources like light and soil water are so limited that suppressed understory trees die and regeneration is severely restricted. In this stage there is usually a continual reduction in the density (number of stems/area) of the original cohort of trees. The structure of the canopy is exceptionally simple at this stage as the individual trees grow in height to co-opt the light resource from neighbors.

In the understory reinitiation stage the overstory begins to break up as canopy trees die and the differential height growth of various species or individuals results in more complex arrangements of the foliage. Increased light reaching the understory favors the establishment and growth of new cohorts of species most capable of surviving in the highly competitive understory environment. The old growth or late successional forest stage is attained as overstory trees age and the canopy develops even greater complexity of structure. Gaps form in the canopy as a result of injury or death of the large, mature individuals, and the previously suppressed individuals are released from severe competition and grow in height. Decaying, coarse, woody debris accumulates on the ground and dead tree snags also provide new habitats for animals. Obviously, this idealized model of forest stand dynamics exhibits myriad local variations depending on the nature of the disturbance, environmental factors, and the tree species that dominate the area.

The changes in forest structure (e.g., foliage-height distributions) that accompany stand development following large-scale disturbance result in consequent gradual shifts in the quality of the habitat for different animals and plants. In the example cited earlier, *MacArthur and MacArthur (1961)* observed that maintenance of high numbers of bird species in eastern deciduous forests of the United States depended on the adequate provision of three layers of foliage, corresponding roughly to ground vegetation (0–2 ft), shrubs and small trees (2–25 ft), and overstory trees (>25 ft). If nearly all the foliage of the forest is in just one layer, as in the stand initiation and stem exclusion stages of stand development, bird diversity is much lower than in the old-growth stage, when canopy stratification becomes prominent.

The nature and degree of vertical stratification differ among forests. For example, temperate deciduous forests in the mature stage often exhibit the three strata just identified: An overstory stratum occupied by the canopy trees, an intermediate stratum represented by the crowns of saplings and understory species like dogwoods and hornbeams, and a ground stratum of low shrubs and forbs. In contrast, in the lowland tropical rain forest, very tall “emergent” trees with broad shallow crowns overtop the main canopy, which may be subdivided into two or more additional strata above the understory layers. And in the boreal forest the low stature and conical crowns of the conifers often preclude the formation of strong vertical stratification. These structural differences contribute to the contrasts in the number of distinct habitats provided for associated biota.

As noted earlier, many forest regions are only rarely affected by large-scale disturbances because they are both too moist to carry fires and not subjected to catastrophic windstorms. In these regions the steady-state forest is characterized as a shifting-mosaic landscape of small patches of different sizes and shapes, each patch reflecting the legacy of disturbance caused by the death of individuals or small groups of overstory trees. Each of the patches may follow a sequence of development analogous to that outlined for large-scale disturbances, but the overall structure of the forest is dependent on the arrangement of the tapestry of patches that comprise the larger forest stand. The edges between these patches and the vertical distribution of structural elements represent important dimensions of the habitat variability that permits species coexistence in forests.

Recognizing the importance of forest structure and pattern for biodiversity, ecologists are developing new, more sophisticated approaches for quantifying these parameters. Because the structural features that are important in determining animal and plant habitats differ among taxonomic groups and forest types, it is unlikely that any single approach will provide a universal standard by which forest structure and biodiversity can be related. Current efforts are utilizing new tools in the areas of spatial statistics, computer modeling, and remote sensing to provide suitable protocols for evaluating the connections between forest structure and pattern, management activities, and biodiversity of various groups of biota. These efforts will provide a better basis for understanding how forest ecology and biodiversity are related.

Food Webs and Community Organization in Forests

A food web is a set of species that live together and a specification of which species “eat” which other species. Plants provide the base of the food web by converting solar energy into biomass; herbivores and detritivores utilize living and dead biomass, respectively, to build their own tissues; and these organisms are in turn consumed by predatory species. Although a connection between the structure of food webs and biodiversity seems axiomatic, the exact nature of this connection is extremely complex. The biodiversity of a particular community is expressed in three different elements of food web structure: (a) the food chain length – the number of trophic links in the food web (producer–1°consumer–2°consumer–3°consumer, etc.); (b) the number of distinct trophospecies – the set of all species that share some particular set of predators and prey – within a trophic level; and (c) the diversity of species constituting each trophospecies.

In forests, as distinct from most other biomes, the first link in the food web is dominated energetically by the detritivores rather than the herbivores. That is, most of the biomass in forests is consumed after the plant tissues die and are added to the soil as detritus. Thus, the detrital food web dominates the energetics of forest ecosystems and much of the complexity of the detrital food web in forests remains to be explored. These energetic considerations are not translated in a simple way to biodiversity in the respective food webs. The variety of different food sources available to herbivores in forests (leaves, stems, fruits, seeds, flowers, and roots of different plant species) provide numerous niches for their diversification, whereas most of the biomass energy available to detritivores is in the form of woody tissues which are structurally and biochemically so similar from species to species of trees that the diversification of wood decay organisms is somewhat limited. For example, one taxonomic group of insects, the higher termites (family Termitidae), overwhelmingly dominates in the comminution and decomposition of plant biomass in many tropical and warm temperate forest biomes. Nevertheless, in comparison with herbivore-dominated biomes (e.g., grasslands, aquatic ecosystems), the role of detritivores in forest biodiversity is probably relatively high.

The interactions of species in the forest community are not entirely competitive and predator–prey in nature. Some of the most fascinating interactions provide selective benefits to both of the interacting individuals or species populations – mutualistic and symbiotic relationships. Mutualism refers generally to a relationship in which two interacting species enhance their survival, growth, or reproduction, while symbiosis refers more specifically to two such organisms living together in close association. The most important symbiotic mutualism in forests is the mycorrhiza, an association between the mycelia of fungi and the roots of trees. The tree roots provide a supply of food to the fungus, which in turn increases the capability of the plant to acquire soil nutrients and water. All forest trees are mycorrhizal, and each tree species may harbor dozens of different fungal species in this mutually beneficial relationship. Two distinct types of mycorrhizae are common in forest trees – the ectomycorrhizae and endomycorrhizae. These types differ taxonomically, anatomically, and physiologically. The possible role of these mycorrhizal associations in regulating

the diversity of forests was pointed out by [Connell and Lowman \(1989\)](#). They observed that pockets of low-diversity forest are found within the matrix of high-diversity tropical rain forest in all tropical regions. These low-diversity forests are composed of trees with ectomycorrhizal associations, whereas most of trees in the high-diversity forest are endomycorrhizal. Functional differences between the mycorrhizal types in soil nutrient acquisition or transfer could maintain or reinforce competitive interactions between individuals in these distinct forest types.

Most mutualisms between plants and animals have developed around the successful completion of the reproductive cycle of the plant – pollination and seed dispersal. Although many trees simply disperse their pollen to the wind, this method of pollination is unreliable when individuals are widely scattered in the forest, as in the species-rich tropical rain forest. Insects, nectivorous birds, and bats visit the plants to exploit them as a source of food and in the process carry pollen from one flower to another. Similarly, plants with seeds too heavy to be dispersed by the wind rely on animals to carry the seeds away from the mother plant. Although in most cases these mutualistic interactions are nonobligate and facultative (at least on one side), many remarkable examples of highly intricate, obligatory interactions have evolved, especially in the tropics. These interactions promote specialization and increased biodiversity.

Human Activity and Forest Biodiversity

Few forests have escaped the effects of human activity. Ancient civilizations decimated forests locally as a source of fuel and fiber and as sites for intensive agricultural production. In the modern era the pervasive influence of industrial civilization on forests has expanded to the regional and global scale through the additional effects of species introductions, air pollution, and likely climatic change. Insights from forest ecology provide a basis to evaluate the implications of these human influences on biodiversity.

Introduction of Alien Species

Alien insects and pathogens typically wreak havoc on host trees because these hosts have not developed adequate defenses through the process of evolution. The result is widespread decline of the host trees throughout their range even to near the point of extinction. The consequences of great reductions in the abundance of such declining species for the wider biotic community are not well understood and undoubtedly vary depending on the characteristics of the declining species (discussed later). Similarly, introductions of other species in different taxonomic groups or at other positions in the food web will have consequences for forest biodiversity that depend on their particular role in the community. Invasive trees may displace congeneric species from the forest community; and introduced herbivores that lack natural controls on their populations may decimate populations of their favored food plant species. Because the pace of species introductions has increased very rapidly in recent

years, the ultimate consequence for forest ecosystems and biodiversity will be played out over the coming century.

Forest Harvest

The consequences of tree harvesting for forest biodiversity depend on particular features of the forest and the methods of harvest. Because all forests are regularly subjected to disturbance, if forest harvest practices mimic the natural disturbance regime, then consequences for biodiversity should be minimal. However, the exigencies of the financial bottom line result in harvest practices that do not mimic natural disturbances, and the consequences of actual forest harvest practices for biodiversity may be substantial. Most serious are (a) logging practices that result in the failure of the cut-over site to regenerate (e.g., because of severe damage to soils); (b) the coincident harvest of extensive areas, so that most of the landscape is in a single stage of forest stand development; and (c) recurring harvest on short rotation intervals. Also, forest harvest differs fundamentally from natural disturbance in that wood products are removed from the site; any species that depends on decaying wood for its habitat will be harmed by harvest practices that do not recognize this dependency. Finally, some species are believed to be old-growth obligates (i.e., they depend on old forests to complete their life cycles). These species are threatened when the great majority of natural, old forests in a region enters the harvest-regrowth system of industrial forestry, leaving little old-growth habitat.

Forest Conversion and Fragmentation

Permanent or semipermanent conversion of forested areas to other land uses has more severe consequences for biodiversity than forest harvest. Many forests occur where climate and soils are suitable for permanent agriculture and where the expansion of urban communities gobbles up native vegetation. Maintenance of biodiversity in such regions depends on having protected forest areas large enough to harbor the native flora and fauna. However, general rules to guide forest preserve planning for biodiversity protection are complicated by variations in the habitat requirements of different species. Forests in most agricultural regions occur as small fragments dispersed across the landscape, and how effectively these fragments can maintain viable populations of forest species is a topic of great concern ([Schelhas and Greenberg, 1996](#)).

Pollution

Local declines of forests has been associated conclusively with point-source releases of air pollutants, especially sulfur dioxide, fluoride, and toxic metals from smelters. Broad scale, regional effects of air pollution on forests have been more difficult to demonstrate. Regional pollution – by ozone smog in the southwestern United States and by acidic deposition in the eastern United States and Europe – probably has contributed to documented forest declines. Although improvements in emission controls and regulations in these regions are likely to reduce the chances of further damage, rapid industrialization without adequate

emission controls in other regions of the world threatens forest health and biodiversity.

Rapid Climatic Change

The Pleistocene epoch was marked by dramatic climatic shifts that profoundly affected forests and biodiversity. The rapid rise in greenhouse gas concentrations is likely to bring about similar climatic shifts in coming decades or centuries. Of course, the consequences of rapid climate change for forests and biodiversity will depend on a combination of species' natural responses (e.g., dispersal, colonization, natural selection) and human mitigation efforts. In many forest regions certain species, like the dominant trees and particular wildlife populations, are likely to be controlled by management efforts because of their relatively high value to humans. For relatively low-valued species and forest regions, the maintenance of biodiversity may depend on natural mechanisms or heroic human efforts that recognize nonmarket values of species. The current level of understanding of the physiological and population ecology of many forest-dwelling taxa is insufficient to predict the effects of rapid climatic change, but species with limited capacity for dispersal and colonization (e.g., soil invertebrates, perennial herbs) may be most sensitive. The implication of the loss of these species from forest communities will vary depending on the role they play in forest ecosystem function.

Biodiversity and Forest Ecosystem Function

Forests regulate energy flow and cycling of materials in the landscape, collectively known as ecosystem functions. The effects of biodiversity, expressed in terms of species richness, on forest ecosystem functions are not yet clear and apparently not very straightforward. There is great interest in these possible effects as ecologists probe the implications of loss of species diversity for the integrity of ecosystems. Will species extinctions result in destabilization of ecosystem functions and possible feedbacks in the form of undesirable shifts in dominant vegetation types?

Although the role of species richness *per se* in regulating forest ecosystem functions remains unclear, it is well known that loss of particular species from the biota of a community can have important ramifications for energy flow, material cycling, and maintenance of stable biotic composition. That is, all species in the ecosystem are not equal in terms of their quantitative influence on ecosystem function. In particular, for some species there appears to be little or no redundancy with respect to their role in the ecosystem; if such a species performs some crucial activity, its loss from a forest can create havoc for the normal functioning of the ecosystem. These species are known as keystone species.

In forests keystone species are represented among many different taxonomic groups or food web positions. For example, at the primary producer level, a nitrogen-fixing tree like *Alnus rubra* in N-poor conifer forests is a keystone species; elephants appear to be keystone herbivores in

semiarid Africa; beavers are keystone "ecosystem engineers" in northern forests; and jaguars that prey on seed predators in neotropical forests may be keystone carnivores. The loss of these species has consequences for ecosystem structure, function, and composition that are out of proportion from their individual abundances. Important efforts to conserve forest ecosystem functions in the face of biodiversity loss are focused on the identification of keystone species and ways of maintaining stable populations of keystone species.

Although the broader effects of overall reductions in biodiversity on forest ecosystem function remain more obscure, a specific example will illustrate that this is also a cause for concern. During the past several decades, excessive inputs of nitrogen (from air pollution) to forests in northern Europe have resulted in striking reductions in the abundance of mushroom species. These mushrooms are the fruiting bodies of ectomycorrhizal fungi discussed earlier. Lilleskov *et al.* (2001) have shown that a single host tree, white spruce (*Picea glauca*), maintains associations with about 90 different mycorrhizal fungi in natural, N-poor forests in Alaska, whereas in adjacent N-polluted forests only about five fungal associates are found. The high diversity of this mycoflora in the natural forest certainly represents some degree of functional redundancy. However, if dozens of species are lost from the mycorrhizal fungal flora in temporarily N-polluted regions, some long-term effects on forest ecosystem function are likely. The fungi in the N-rich forests appear to utilize only the mineralized nitrogen sources NH_4^+ and NO_3^- , which are abundant there; with a return to normal, low-mineral N availability, in the absence of mycorrhiza that access organic N forms, the productivity and nutrient cycling in the forests could be altered profoundly. Analogous situations probably apply in other aspects of both the detrital and grazing food webs of forest ecosystems around the world.

Glossary

Alien species A species introduced from another region or ecosystem.

Globalization The process engaging financial markets to operate internationally, largely as a result of increased trade, transportation, and communications.

Homogenization A blending of species throughout the globe largely as a result of trade and transportation.

Invasive species A species from another country or ecosystem that causes economic or environmental harm, or harms human health.

Native species A species that evolved and is naturally distributed in the region.

Introduction

The trade of goods by humans has bridged the continents, in effect restoring the old supercontinent of Pangaea. In the past century, humans have been responsible for an exponential increase in plant migrations, moving plant species around the globe for food, fuel, forage, horticulture, landscaping, and medicines. Trade within and among continents is breaking geographic barriers and providing long-range dispersal for seeds and propagules at unprecedented rates (Richardson *et al.*, 2000; Wilson *et al.*, 2009). Here, the authors provide a brief review of the globalization effects on common plant species and “homogenization” of the world’s plant communities.

It’s All About Trade

Globalization is a process that occurs when the trade in goods and service is no longer limited by the physical and administrative barriers that separate countries. Local trading has been a common feature within many cultures. Through human expansion around the globe, increasingly reliable and quick forms of transport, and fewer restrictions on human movement, trade now operates at a global scale. The dawn of long-distance merchant ships in the Minoan, Greek, and Roman civilizations connected Europe, Africa, and Asia. As long ago as 67 BC, the Roman Empire had cargo ships carrying 70,000 kg of grain and other supplies from far and wide (Kessler and Temin, 2007). Indeed, many current invasive plant species in Italy can be traced to early trade. Trade in crops accelerated in the Old World in the mid-eighth to mid-thirteenth centuries AD, with Arab people bringing a range of

food items to the Mediterranean. In the New World, Native Americans were trading obsidian, shells, tobacco, maize, squash, and dozens of other plant products.

In the fifteenth to seventeenth centuries AD, the Age of Discovery accelerated the global exchange of agricultural products. Foods such as potatoes, tomatoes, maize, and other agricultural crops, for instance, moved from the New World to the Old World (Crosby, 1972). In the late eighteenth century, the isolated southern-hemisphere continent of Australia was brought into somewhat permanent connection with the rest of the world, when it was established by the British as a penal colony. Since then, over 26,000 alien plant species have been introduced to Australia with periods of high influx over this time (Phillips *et al.*, 2010).

International trade skyrocketed between 1870 and 1913 and after 1950, the volume of world trade merchandise increased seventeen-fold (Flemming, 2004). In the modern day, most of the goods consumed by humans stem from imports (Figure 1). As the global economy expanded, so did trade in live plant materials, with ornamental horticulture an important source of introduced invasive plants (Reichard and White, 2001). For example, Maki and Galatowitsch (2004) found that prohibited alien species in Minnesota were acquired in 92% of orders they placed with 34 aquatic plant vendors across the United States. Additionally, 93% of orders contained a plant or animal species not specifically requested, including several additional prohibited taxa. The advent of e-commerce has turned every home and office computer into a virtual port of entry. Live plants and seeds can be mailed to most addresses in many countries.

The comparison between regions with similar climates but with different history of trade may help to elucidate the causes

Figure 1 The boom in the shipping trade, reproduced from the website (<http://maps.grida.no/go/graphic/the-boom-in-shipping-trade1>), and based on John Vidal, "Shipping boom fuels rising tide of global CO₂ emissions," The Guardian, February 13, 2008; Atlas du Monde Diplomatique 2006, Armand Colin; Panorama des ports de commerce mondiaux 2003, ISEMAR, January 2005; Images économiques du monde 2002, Sedes.

of current patterns of homogenization. For example, although central Chile and California share a similar Mediterranean climate, the history of massive introductions in the last two centuries have favored a much more diverse alien flora in California (*ca.* 1200 species) (Jiménez *et al.*, 2008). Interestingly, the Chilean alien flora (*ca.* 600 species) is almost completely a subset of its counterpart, including 25 species native to California. Central Chile has a much stronger influence of European species, and because of its higher commercial trade and diverse immigration history, California has a more cosmopolitan flora with a higher proportion of species from Asia, Africa, Australia, and other regions of the Americas.

Homogenization of Biota

Today, plant species from the modern nursery trade often do not stay in their port of entry or primary destination (Reichard and White, 2001). Wind, water, birds, and other animals (including humans), carry propagules to many destinations, where they grow and reproduce. The naturalization of alien species is further facilitated by urbanization, agriculture, and grazing by domestic livestock. The combination of trade,

human-caused land use change, and extinction of native species result in biotic homogenization across the globe (Sax *et al.*, 2002). Homogenization is defined as the increasing similarity of species composition due to the concurrent extirpation of rare or even unique native species, and the increase of common, widespread alien species primarily due to the effects of modern humans on the rate of change (McKinney and Lockwood, 1999). Generally, local species assemblages lose their uniqueness, affecting also their conservation value (Pino *et al.*, 2009; Winter *et al.*, 2009). Researchers are just beginning to explore patterns of homogenization at inter-continental and global scales using species frequencies and abundances to provide a more complete view of biotic homogenization (Winter *et al.*, 2010). However, in most regions of the world alien invasions exceed regional extirpations, and hence species richness increases (Stohlgren *et al.*, 2008).

Uneven Results of Globalization

So to what extent have floras become globalized? The degree to which a flora is composed of alien species has most often been measured by the relative numbers of native and alien

species. However, how widespread alien species are in invaded regions is an equally important measure of their success. Recently, a team of scientists from around the world collated the best available data from several countries and regions to see if alien plant species were as widely distributed as native plant species (Stohlgren *et al.*, 2011).

There are, of course, profound differences in how native and alien floras have developed. Native species have had evolutionary time to disperse into the available ecological niches in their respective regions. If alien plant species became equally as widely distributed as native species in a much shorter time, this would indicate that alien plant species and the introduction processes are functioning, in terms of distributional range, in a similar way to native plant species. However, even if this was true, there would still be a principle difference in that these processes would have been operating much faster than in native species, possibly reflecting extraordinary dispersal abilities of aliens and their high competitiveness in colonizing new habitats, for reasons believed to determine the success of alien invasive species (Pyšek and Richardson, 2007). If aliens are more widely spread than natives, this would indicate that part of the invasion process is operating differently to background distributional range expansion and occupancy (i.e., the alien species are different, the environment has changed to favor aliens, or human-assisted dispersal enables aliens to gain wider distributions). If aliens have narrower distributions than natives, this suggests that either aliens tend to not succeed widely across a new range of environments, or that these species have not reached their distributional limits, and that we may only be on the cusp of a homogenization tsunami.

The team of scientists gathered information on the distributions of the 120 most widely distributed plant species in various region of the world, based on their frequency in

defined subregions (ecological zones or administrative units) or grid cells (typically 10 km × 10 km). Species were characterized as “native” or “alien,” the latter being plant species not native to the biogeographical region or country, having arrived by means of human activities. The initial cutoff point of 120 species was arbitrary, but based on general knowledge of plant frequency distributions (Stohlgren, 2007). The sample sites differed greatly in area and species richness, so they also evaluated the top 120 species in three US states (California, Texas, and Florida), and three European regions (Great Britain and Ireland, the Czech Republic, and Catalonia in Spain) to see if patterns held at smaller spatial extents. What they found surprised them.

First, there were large differences between areas in the percentage of the widespread floral species that was alien (Figure 2; Stohlgren *et al.*, 2011). In North America, over half of the most widely distributed species were from other continents, primarily Eurasia. Alien plant species were also well represented in regions of Australia, South America, and South Africa, where they contributed between 22% and 43% to the total number of most widely distributed species, but European regions contained few widespread aliens, <2%, despite thousands of years of long-distance trade in plants. Second, individual subregions in Europe and North America varied considerably in the percentage of aliens on the 120 most widely distributed species lists (Figure 2). In subregions, the percentage of aliens can be greater or less than that of the surrounding region. For example, California with 5688 total native plant species had 20% aliens on the list, while Florida, with 3284 total native plant species had only <1% (Stohlgren *et al.*, 2011). Third, the most surprising and consistent finding, was that aliens on the lists were as widely distributed as their native species counterparts, regardless of scale and extent of the study areas. Aliens were significantly more widely

Figure 2 Relationship of percent alien species in the 120 most widely distributed species in a region. Reproduced from Table 1 in Stohlgren TJ, Pyšek P, Kartesz J, *et al.* (2011) Widespread plant species: Natives vs. aliens in our changing world. *Biological Invasions*. doi: 10.1007/s10530-011-0024-9, with permission from Springer.

distributed than native plant species in North America, Argentina, Chile, and the Republic of South Africa, and equally widely distributed as native species in California, Texas, Florida, and throughout Europe.

Donor and Receptor Regions

To evaluate donor and receptor regions for common plants around the world, it is helpful to assess how common plant families overlap across continents. Broadly spread plant families include Asteraceae, Brassicaceae, Poaceae, and Fabaceae. Likewise, many families often overlap between native and alien species within countries or regions. In the aforementioned study by *Stohlgren et al.* (2011), the Poaceae and Asteraceae were more broadly spread in North America, South Africa, and New South Wales (across origin status). The Rosaceae family included widely spread native and alien species in Great Britain and Ireland.

In terms of particular regions, Europe and Asia contributed many species to lists of widely distributed species in the New World (*Stohlgren et al.*, 2011). As such, Europe appears to be a better donor than receptor of plant species (Pyšek, 1998; Winter *et al.*, 2009; **Figure 2**), while North America proves to be a melting pot of its flora. However, every region on the globe must be considered a potential donor of alien species.

Stohlgren et al. (2011) also found many examples of widely distributed species, which help us to understand donor and receptor regions for plants. For example, *Chenopodium album*, contains varieties from Europe (*Chenopodium album* var. *album*) that are now widely dispersed in North America. Likewise, *Cirsium vulgare*, a native species in Europe, is a widely dispersed alien species in other parts of the world. In these cases, widely distributed native species became widely distributed alien species. The scientists also found that some species were more widely spread in their invaded habitat compared to their native homelands. *Senecio vulgaris* ranges broadly in Catalonia, and less so in Great Britain and Ireland, but was widespread throughout North America. Likewise, *Agrostis stolonifera*, a species native to the United States and temperate Europe, was found to be narrowly ranged in Great Britain and Ireland, but less so in Catalonia, and a widespread weed in Chile. However, *Bromus tectorum*, a well known Eurasian invader in North America, did not appear on any other New World lists. Likewise, *Opuntia ficus-indica*, is the most widely distributed alien invader in South Africa, and is now common in Argentina, but is not as relatively widespread in its native Mexico.

Selected Examples

There are many examples of common plant species now spreading around the world. Knowledge of the distributions of native and alien species around the globe provides the opportunity to understand the traits of highly invasive species, and thereby develop effective monitoring and prevention programs against the harmful spread of invasive species. The following examples serve to illustrate the global and continental scales of invasions (**Figure 3**).

Water Hyacinth (*Eichhornia crassipes*)

Water hyacinth is a perennial, free-floating aquatic plant native to tropical regions of South America, and now present on all continents except Antarctica. Plants rapidly increase biomass and form dense mats, reproducing from stolons (i.e., vegetative runners). Water hyacinth can completely cover lakes and wetlands, outcompeting native aquatic species, reducing oxygen levels for fish, and creating ideal habitat for disease-carrying mosquitoes. Large infestations of water hyacinth can prevent river transport, fishing, damage bridges, and clog dams. Lake Victoria, Africa, and the water-ways of Papua New Guinea are prime examples where massive populations have limited transportation and fishing, and increased the incidence of diseases (*Masifwa et al.*, 2001).

Within the US, water hyacinth is thought to have been introduced to Louisiana in the 1880s, and released later in the St. John's River in Florida. Enthusiasts distributed it around the world and water hyacinth was naturalized in Egypt, India, Australia, and Java well before the end of the nineteenth century. It is now found across the tropics and in some subtropical countries, for example, New Zealand and Portugal. Despite regional bans on its transport, and various control efforts, it has invaded many new areas particularly in Africa. Water hyacinth is a popular aquarium plant, and can be purchased at many aquatic plant nurseries and online distributors around the world.

Castor Oil Plant (*Ricinus communis*)

Native to Africa and the Middle East, Castor oil plant is a member of the spurge family, Euphorbiaceae. It produces seeds containing between 40% and 60% oil rich triglycerides. The plant is a fast growing shrub or tree that can reach a height of 12 m or more in tropical areas. Today, the plant is widespread in tropical regions of the world, largely as a crop. Castor seed production is around one million tons per year, with major growers in India, China, Brazil, and Ethiopia (www.faostat.fao.org). Horticulturists have created and sold several cultivars as landscaping trees and shrubs, adding to its spread. The seeds of this species, which are commercially widely available, are dispersed by both wind and ants over long distances. Once established, castor oil plant can invade natural areas such as those found in Hawaii, Florida, and elsewhere, creating problems for land managers trying to contain this fast-growing plant.

Alligator Weed (*Alternanthera philoxeroides*)

Alligator weed, native to South America, is an amphibious plant species in the Amaranthaceae family. It has become highly invasive in China, Australia, New Zealand, Thailand, and the United States. Like water hyacinth, it grows quickly to reduce water flow, canopy light, and oxygen levels in the water column, thus reducing habitat quality for various wetland species. However, alligator weed can also invade dry lands and agricultural fields. In the US, it has become a species of great concern in south Texas, and throughout most of Florida. In the US, it has now spread to 337 counties and 15 states, with recent records extending as far north as Virginia and Illinois. It

Figure 3 Maps of selected alien species at global scales, and in the United States.

spreads easily as small stem fragments can quickly produce new plants.

St. John's Wort (*Hypericum perforatum*)

St. John's wort is a yellow-flowering perennial herb native to Europe, grows wild in North America, Asia, India, Australia, South Africa, and many islands. It is a member of the Hypericaceae family (formerly placed in the Clusiaceae

family), with a long history of human uses including warding off evil, and serving as an antidepressant. St. John's wort is currently treated as a noxious weed in many areas, because high concentrations of hyperforin and hypericin make it toxic to livestock. Throughout the US, populations of St. John's wort can be found in rocky open ground, wooded areas, and meadows. Seeds, which adhere to wildlife and livestock for easy dispersal are commercially available for wildflower plantings.

Spanish Needle (*Bidens pilosa*)

Spanish Needle (*Bidens pilosa*), an annual member of the Asteraceae family, has long been called Hairy Beggarsticks (in the US). The species is native to South America, but it is now commonly established throughout tropical and subtropical areas of the world. It is also common on many islands in the Indian Ocean. Spanish Needle can dominant plant cover in cultivated fields, plantations, and other cultivated and ruderal areas. Considered one of the most noxious annual weeds in East Africa, it invades fields of over 30 crops and is now well established in more than 40 countries (Holm *et al.*, 1991). The plant is thought to produce allelopathic toxins that affect a number of crops. The colorful white and yellow flower produces 1.8 cm long barbed seeds that adhere to the legs of humans and other mammals, representing an effective means of dispersal. In some parts of the world, such as in sub-Saharan Africa, the plant is used for food or medicine (Grubben and Denton, 2004).

Giant Hogweed (*Heracleum mantegazzianum*)

One of the most impressive invader weeds of Europe is the Asian hogweed genus (*Heracleum*) of the family Apiaceae. Several members of the genus were introduced as garden ornamentals or as fodder crops outside their native range. The most distinctive characteristic of these closely related species is their conspicuous appearance; they can attain heights of up to 4–5 m, which ranks them among the tallest and largest herbs in Europe. The most widely distributed member of the genus, giant hogweed (*Heracleum mantegazzianum*) produces phototoxic sap, dangerous to humans. The first known record of this species was reported in Kew Botanic Gardens, London in 1817. In 1828, the first naturalized population was recorded in the wild in Cambridgeshire, England. Soon afterwards, the plant began to spread rapidly across Europe; and is currently recorded from 19 European countries. A likely reason for its widespread distribution in Europe is due to multiple introductions, as suggested *via* genetic analysis of invading and native populations of this species. Giant hogweed has a number of characteristics that contribute to its invasiveness: including its extremely high fecundity, rapid growth rate, capability of selfpollination, extended germination period by means of short-term persistent seed bank, high germination, and negligible impact of natural enemies (Pyšek *et al.*, 2007).

Implications

For reasons still unknown to us, some geographic areas are more easily invaded than others (Richardson *et al.*, 2005). General observations suggest that areas with high numbers of native species are vulnerable to invasions due to high resource availability and high environmental heterogeneity – a pattern that holds up generally well over large portions of the earth from local and regional scales (Stohlgren *et al.*, 1999; 2003) to global scales (Lonsdale, 1999). Increasing trade and transportation diminishes dispersal limitations, and increases the number of introductions and species overlap among regions and nations (Pyšek *et al.*, 2010). The number and overlap of

alien taxa among countries or regions (Stohlgren *et al.*, 2011) is a testament to trade and transportation. However, the paucity of widely distributed alien species in Europe remains an aberration. Very few of the 1600 plant species that were introduced to Europe since AD 1500 have become widespread (Lambdon *et al.*, 2008). The approximately 11,000 native plant species seem to be holding their ground.

Climate, level of disturbance, time since introduction, and trade volume are often given as reasons for differences in invasion patterns. However, geographic areas within the Peoples Republic of China, North America, and portions of Europe include temperate zones with very different invasion patterns. All these areas are heavily affected by land use change. The early plant invaders in Europe (pre AD 1500) showed that as a group, they are equally distributed despite widely different times since introduction (Pyšek *et al.*, 2002; Stohlgren *et al.*, 2011). Increased volume of trade and transportation with Peoples Republic of China, a country very rich in species diversity, may create additional future challenges for other countries and regions. Europe, especially its Mediterranean region, has been traditionally considered a donor of invasive species to other parts of the world due to historical reasons and its long association of plants and animals with humans since the beginning of agriculture some 10,000 years ago. This is reflected by the majority alien species on other continents being of Eurasian origin (Pyšek, 1998).

Regional and national plant inventories and databases are essential to understand patterns of invasions. Many areas of the globe may lose their floristic uniqueness as plant species continue to invade. Trade and transportation and changing patterns of widely distributed species will most likely dominate future patterns of biodiversity. We may be witnessing accelerating effects of the great reshuffling of species on the globe as geographic isolation diminishes over time. Human-assisted migrations, and unintentional species establishment followed by natural dispersal by wind, water, and animals may further spread alien assemblages from local to global scales. While the scientific community is making great strides in tracking global invasive species, it might be prudent to begin thinking about the tracking of widely distributed native species as likely donor populations.

© 2013 Elsevier Inc. All rights reserved.

This article is a revision of the previous edition article by J. P. Grime, volume 3, pp. 329–337, © 2001, Elsevier Inc.

Glossary

Dominant species Species that have the greatest influence on ecosystem structure and function by virtue of their abundance, biomass, or coverage.

Mass ratio hypothesis Hypothesis stating that ecosystem processes are largely determined by the dominant contributors of the overall plant biomass, that is, dominant species will exert greater influence on processes than will subordinate species.

Species richness Number of species present in a given habitat or ecosystem.

Subordinate species Species that have a minor influence on ecosystem structure and function, presumably because of their lesser abundance and biomass compared to dominant species.

Transient species Species that are present as scattered seedlings or small immature individuals; many of these species occur as dominant or subordinate species in neighboring vegetation associated with different environmental conditions or management regimes.

Introduction

Ecological research into losses in plant diversity has a long history, but in recent decades the agenda has shifted from a primary concern with its mechanisms to an assessment of the extent to which losses impair the functioning of ecosystems and reduce their utility to humankind. It is relatively easy to manipulate the species composition and diversity of herbaceous communities in both natural and model ecosystems, and experimenters have applied themselves with vigor to this new field of inquiry. The objectives in this research are two-fold. First, one must identify where and how losses in diversity affect ecosystem functions such as primary productivity, carbon storage, mineral nutrient cycling, and ecosystem resistance and resilience. Second, information is required on the plant constituents necessary for successful ecosystem restorations; it must be established which plant species are irreplaceable and what population sizes and pools of genetic variation are required for their persistence.

As participants in both the current and the preceding phases of research on plant diversity, the authors emphasize the value of connecting theory and data from the earlier phase of research into the causes of plant diversity to more recent efforts that examine its consequences for ecosystems. The main objective of this article is to identify these connections. An additional purpose is to highlight opposing perspectives of whether the traits of dominant species or species richness itself have a primary role in ecosystem functioning.

Controls of Species Richness in Herbaceous Vegetation

Species Richness Peaks at Intermediate Levels of Disturbance and Productivity

The humped-back model (HBM) was proposed (Grime, 1973) as a compact scheme to describe the controlling effects of

five factors (productivity, disturbance, dominance, niche-differentiation, and the local species pool) on the species richness of a plant community. Along a gradient of standing biomass, plant species richness increases as rates of disturbance or environmental stress decrease, to a maximum determined by the size of the local species pool and the degree of local environmental heterogeneity. Continuing along the gradient, ecosystems of high productivity and low disturbance rates favor species capable of quickly usurping available resources, which leads to rapid declines in richness from competitive exclusion. Four decades of testing have shown that the HBM is compatible with a large volume of plant community data, particularly at fine spatial grains (Grace, 1999). Unresolved aspects of HBM include the extent to which niche-differentiation is important in species-rich communities (Silvertown, 2004) and the general contribution of dispersal limitation in the context of regional species pools (Helm *et al.*, 2005).

Role of Intraspecific Diversity

More recent research on linkages between species diversity and intraspecific genetic diversity has suggested that the process of competitive exclusion may be slower in communities where populations exhibit high local genetic differentiation (Vellend and Geber, 2005). For example, in the species-rich calcareous grasslands of northern England inhabited by outcrossing perennials that exhibit high local genetic and morphological variation, genetically diverse populations maintained higher species evenness in an experimental setting (Booth and Grime, 2003; Fridley and Grime, 2010), which was due in part to the genotypic dependence of species-level competitive relationships (Figure 1; Fridley *et al.*, 2007). The role of intraspecific genetic diversity in maintaining high species richness seems to be greatest when disturbance (e.g., grazing or mowing) reduces the importance of apical dominance as a 'best strategy' for competitive superiority (Herben *et al.*, 2001), but more

Figure 1 Left panel: The competitive dominant in pairwise competition between a sedge (*Carex caryophyllea*, gray bars) and a grass (*Koeleria macrantha*, black bars) in a pot experiment depended on the genetic identity of each species (rows are three genotypes of *Koeleria*, columns are three genotypes of *Carex*, all propagated from mature individuals growing together in the field) 2007. This suggests competitive exclusion in genetically diverse populations is slow particularly in cases of disturbance (e.g., grazing) and low resource availability. Right panel: the same competitive relationships under more fertile, less disturbed conditions. Here there was no influence of genotypic identity on the outcome of competition. Reproduced from Fridley JD, Grime JP, and Bilton M (2007) Genetic identity of interspecific neighbors mediates plant responses to competition and environmental variation in a species-rich grassland. *Journal of Ecology* 95: 908–915, with permission from Wiley.

studies are needed before the overall significance of intraspecific diversity to species richness is understood.

Plant Traits, Species Richness, and Ecosystem Functioning

Effects of Plant Traits on Ecosystem Properties

Although the majority of investigations in plant ecophysiology have sought to explain how vegetation is determined by environment, there has also been widespread recognition of feedbacks in which plants affect their environments and influence ecosystem properties. This idea is implicit in the writings of the founders of ecosystem theory (Odum, 1963, 1969) and more recently has found expression in the search for plant functional types (Grime, 1979; Chapin, 1980; Smith *et al.*, 1996; Diaz *et al.*, 2004), in which specific plant community and ecosystem properties have been attributed directly to particular plant traits such as potential growth rate, palatability to herbivores, resistance to fire, litter quality, and seed persistence. This approach has been extended further by studies in which the predictive value of plant traits has been tested by examining ecosystem responses to perturbation. An early example is the investigation by Leps *et al.* (1982) in which differences between two neighboring grasslands in their resistance and resilience following the severe drought of 1975 in the Czech Republic were predicted from the life histories and potential growth rates of the main component plant

species. More comprehensive tests were conducted by MacGillivray and Grime (1995), in which responses to frost, drought, and fire in five contrasted grasslands were successfully predicted from a set of plant traits measured in a laboratory screening program (Grime *et al.*, 1997).

The Mass Ratio Hypothesis

It is important to note that in tests such as those conducted by MacGillivray and Grime (1995), predictions are weighted according to the abundance of each plant species in the vegetation; this is founded on the assumption that the extent to which the traits of a species affect ecosystem properties is likely to be strongly related to the contributions of the species to processes such as photosynthesis, mineral nutrient capture, transpiration, and provision of substrates exploited by herbivores and decomposers. There is a clear implication here that ecosystem processes are determined to a large extent by the characteristics of the dominant contributors to the plant biomass. As a corollary of this “mass ratio hypothesis” (Grime, 1998), one would not expect minor contributors to the vegetation to exert strong effects on ecosystem properties.

Is it reasonable to conclude that ecosystem functions can be sustained by inputs originating from only a few dominant plant species? Some of the most extensive ecosystems contain very few plant species; this is particularly obvious in grasslands and heathlands on acidic soils, and here the conclusion is

Figure 2 Vertical distribution in the leaf canopy of four dominant and four subordinate component species in an ancient limestone pasture at Buxton, North Derbyshire, England. Canopy distribution in June was estimated by measuring contacts with 375 randomly distributed, vertical pins. Reproduced from Hillier SH, unpublished data.

inescapable that controls on ecosystem processes by vascular plants are mediated through very few species. In herbaceous vegetation on soils of higher base status, analysis is complicated by the presence of more species, and in old calcareous grasslands the densities of herbs can rise to 30–40 species per m^2 . Even here, however, it is interesting to note that when quantitative studies are made by harvest methods (Al-Mufti *et al.*, 1977) or point analysis (Mitchley and Grubb, 1986; see also Figure 2), it is evident that in comparison with the canopy dominants, many of the subordinate species of such communities account for a very small proportion of the biomass. There must be considerable doubt as to whether such minor components can, even collectively, exercise immediate effects on properties such as productivity, carbon storage, and water relations.

Effects Associated with High Species Richness

Against a theoretical background in which the traits of dominant plants were widely suspected to be acting as the overriding controllers of ecosystem properties, considerable interest and controversy were generated in the 1990s when studies began to demonstrate the immediate benefits to ecosystem properties arising from high species richness in experimental plant assemblages (Naeem *et al.*, 1994; Tilman and Downing, 1994; Hector *et al.*, 1999; Tilman *et al.*, 2001). In each case it was suggested that benefits arose in the species-rich mixtures from the presence of a wider range of morphologies and physiologies, generating either complementary and more complete exploitation of resources (Naeem *et al.*, 1994; Hector *et al.*, 1999; Tilman *et al.*, 2001) or

conferring resistance and resilience in the face of an extreme event (Tilman and Downing, 1994). Interest in these publications extending beyond the realm of ecology was stimulated by commentaries suggesting that studies of this kind provided a justification for the conservation of species-rich ecosystems (Kareiva, 1994, 1996; Naeem *et al.*, 1999).

An alternative perspective of these studies was drawn by others (e.g., Aarssen, 1997; Garnier *et al.*, 1997; Huston, 1997; Grime, 1998; Hodgson *et al.*, 1998), who argued that ecosystem properties attributed to high species richness were in reality due to the presence in the more diverse communities of dominant species with traits attuned to high productivity (Naeem *et al.*, 1994) or drought response (Tilman and Downing, 1994). More recent syntheses of a growing body of experimental studies examining richness-ecosystem functioning relationships have suggested that species complementarity can be important in some systems, but monocultures often outperform species mixtures (Cardinale *et al.*, 2006). Although the idea that plant species richness is a significant control over ecosystem processes like productivity continues to generate debate (Thompson, 2010), the overriding significance of the traits of plant dominants to ecosystem functioning is apparent from the large growth in trait-functioning studies (Lavorel and Garnier, 2002; De Deyn *et al.*, 2008; Suding *et al.*, 2008).

Components of Species Richness: Dominants, Subordinates, and Transients

Dominants and Subordinates

Early efforts to describe and interpret herbaceous vegetation (e.g., Clements, 1905; Tansley, 1939; Ramenskii, 1938) involved listing of the plants present in selected stands of vegetation and estimating the abundance of each species. Even before the widespread adoption of experimental approaches, there was a keen awareness of the potential of certain species to occupy a high proportion of the plant biomass and to control the abundance and fitness of other minor contributors. A classic example is the rapid expansion of tall coarse grasses and the coincident suppression of small herbs noted by Tansley and Adamson (1925) in their study of the consequences of excluding rabbits from chalk grassland.

A more quantitative approach followed as plant ecologists adopted stricter sampling methods and measured the relative abundance of plant species by harvesting, sorting, and weighing vegetation samples. This allowed more formalized attempts to examine the functional relationships between dominant and subordinate members of plant communities (Whittaker, 1965; McNaughton, 1978). Subsequently, it was recognized that the potential to dominate vegetation could be associated with specific plant traits such as canopy height, lateral spread, and the capacity to project shoots forcefully through litter and herbaceous cover (Al-Mufti *et al.*, 1977; Sydes *et al.*, 1981a, b; Grubb *et al.*, 1982; Campbell *et al.*, 1992). A further step in defining the functional differences between potentially dominant and subordinate members of plant communities became possible through the application of foraging theory to plants. From a study of the development

of the roots and shoots of isolated plants exposed to standardized patchy environments (Campbell *et al.*, 1991), it became possible to predict the dominance hierarchy that developed when eight herbaceous species were grown together in an experimental assemblage (Figure 3). In this investigation it was found that dominance was associated with relatively imprecise foraging both above and below ground. Such coarse-grained foraging allowed the exploitation of a large volume of habitat but was associated with an imprecise concentration in

Figure 3 An examination of the relationship between root and shoot responses to resource heterogeneity in eight herbaceous species of contrasted ecology. A description of the methods used to expose the plants to resource patchiness is provided in Campbell, *et al.* (1991). Scales of foraging by the roots and shoots in the foraging assays are expressed at the respective increments of biomass (mg) to two undepleted quadrants, which in both assays constitute 50% of the available volume. The vertical and horizontal bars indicate 95% confidence limits. The numbers in parentheses refer to the species ranking in a conventional competition experiment in which all eight species were grown together in an equiproportional mixture on fertile soil for 16 weeks. Note the tendency for the scale of leaf canopy adjustment to exceed that of the root system. This of course arises from the freedom of movement of leaves in air and the encasement of roots in soil. Key to species: Ae, *Arrhenatherum elatius*; Be, *Bromus erectus*; Cf, *Cerastium fontanum*; Cr, *Campanula rotundifolia*; Hp, *Hypericum perforatum*; Km, *K. macrantha*; Pt, *P. trivialis*; Ud, *Urtica dioica*. Reproduced from Fig. 14 of Grime (2001) *Plant Strategies, Vegetation Processes, and Ecosystem Properties*, published by Wiley.

resource-rich sectors. In marked contrast, subordinate species were characterized by precise but local placements of roots and shoots in resource-rich patches, a foraging pattern permitting temporary coexistence with dominants but apparently committing them to a minor status in the community and leaving them vulnerable to extinction in circumstances where the dominants continued to enjoy unrestricted growth.

These findings raise important questions concerning the ecology and evolution of the very large numbers of plant species that consistently occupy subordinate positions within the hierarchies of herbaceous communities. Are these plants merely “also-rans” in the struggle for existence or are there fitness benefits associated with playing a minor part in plant communities? What is the precise role of subordinates in the long-term functioning and dynamics of ecosystems? These are not trivial questions in view of the fact that it is the subordinates rather than dominants that account numerically for the existence of high species richness in plant communities. Detailed attempts have been made to address these issues (Grime, 1987, 1998); here argument will be reduced to the following propositions:

1. Many subordinates achieve widespread occurrence because they are capable of exploiting similar niches associated with different dominant species. For example, *Poa trivialis*, the commonest vascular plant species of Lowland Britain, occupies shaded microhabitats beneath tall grasses, broad-leaved herbs, and a variety of shrubs and trees.
2. In many species-rich communities, the risks to subordinates of competitive exclusion remain low because potential dominants are restricted in vigor by environmental and biotic factors (e.g., mineral nutrient stress, drought, grazing, fire).
3. Because they do not experience the costs in support materials and construction time incurred during the building of robust root and shoot architectures, subordinates enjoy a temporary advantage when communities are subject to episodes of biomass removal. Where damage is catastrophic, as in tree felling and coppicing or the ploughing and burning of grasslands (Skutch, 1929; Marks, 1974; Platt, 1975; Bormann and Likens, 1979; Pickett and White, 1985; Pons, 1989), this can lead to a temporary but massive expansion of subordinates until such time as the dominants recover.

It can be concluded therefore, that many subordinate members of plant communities achieve high levels of fitness,

particularly where natural or human-inspired interventions restrict the vigor of potential dominants either continuously or intermittently. Later in this article, it will be suggested that, in the long term, this rather opportunistic ecology displayed by subordinates may be sufficient to allow them an indirect but crucial involvement in the determination of ecosystem properties.

Transients

Many published records of the species composition of vegetation are incomplete. This can arise from cursory sampling and recording or from a deliberate policy of discounting minor constituents. Where the objective is to recognize recurring plant communities, data analysis often involves procedures that exclude species of low frequency or inconsistent occurrence in vegetation samples. The result of these various decisions can be a divergence between published data and field reality, and it has been suggested (Grime, 1998) that important information relevant to the long-term dynamics of ecosystems may be lost. To examine this hypothesis it is necessary to refer to surveys in which a strenuous attempt has been made to include all the plant species present in the vegetation.

During the period 1965–1975, a series of vegetation surveys was conducted to produce an inventory of the herbaceous plant communities of the Sheffield region in north-central England (see Grime *et al.*, 1988, for details). In each of approximately 10,000 m² quadrats, a complete list of species was made and the frequency of each species was recorded. When the resulting data were examined, it became apparent that, in addition to dominants and subordinates, the majority of the samples contained species that were represented only as scattered seedlings and small immature individuals. Most of these species were present as dominants or subordinates in neighboring vegetation associated with different environmental conditions or management regimes. Examples of this phenomenon are provided in Table 1 for three contrasted sets of vegetation samples; in each case it is evident that the plant communities examined were harboring juveniles of species that occur as persistent, reproductive populations elsewhere in the landscape in vegetation of a different type.

Therefore, it seems reasonable to conclude that in addition to the dominant and subordinate members of a community, a third contributor to species richness can be identified in the form of transients originating either from the seed rain from

Table 1 Ecological classification of the species recorded in three distinctive and highly contrasted habitats sampled widely in an area of 2400 km² around Sheffield, UK^a

Sampled habitat	Number of m ² samples	Woodland species	Grassland species	Arable species	Others ^b	Total
Woodland on limestone	51	65	23	1	5	94
Meadows	40	7	64	8	0	79
Cereal arable	55	5	38	69	2	114

^aAll the species encountered within a particular habitat were classified in terms of their primary habitat (columns 3–6). Details of the sampling, recording, and habitat classification procedures are provided in Grime JP, Hodgson JG, and Hart R (1988) *Comparative Plant Ecology: A Functional Approach to Common British Species*. London: Uwhin Hyman.

^bIncludes species primarily associated with wetland or skeletal habitats (cliffs, walls, and rock outcrops).

the surrounding landscape or from seed banks occurring as a legacy of previous vegetation types that occupied the site.

Declining Species Richness and Ecosystem Reassembly

If immediate control of the functional properties of an ecosystem rests with dominant plants and if species-richness depends on the numbers of subordinates and transients, it is pertinent to ask “Does a decline in species richness matter?” To address this question, it is necessary to consider the significance of losses of subordinates and transients in the long-term dynamics of plant communities and ecosystems.

Filter Effects of Subordinates?

One mechanism whereby losses in subordinates could affect ecosystems is through alteration of the filter controlling the recruitment, identity, and relative abundance of dominants. To review the opportunities for subordinates to control the admission of dominants into communities, it is necessary to consider the long-term dynamics of vegetation and the regenerative phases in the life cycles of dominants. Studies of vegetation succession conducted earlier this century (e.g., Watt, 1925, 1947) established that continued dominance by particular species is frequently determined by the success of seedling or vegetative reestablishment following disturbance events. As already described here, often the early course of events following a disturbance is a temporary expansion in the cover and vigor of subordinates. This is most obvious in forest clearings where a dense, low cover of shrubs, herbs, and bryophytes characterizes the environment of regenerating trees (Watt, 1925; Skutch, 1929; Marks, 1974; Bormann and Likens, 1979), but similar phenomena have been described for grasslands and heathlands (Oosting, 1942; Keever, 1950; Hillier, 1990). Establishment following disturbances involves complex interactions of seedlings and vegetative shoots with substratum conditions, and contributions to the ground cover by subordinate plants may be expected to have both positive and negative effects (Pickett and White, 1985). Benefits to establishment have been described in circumstances where seedlings survive in the shelter afforded by low-growing shrubs, herbs, and bryophytes. Detrimental effects of shrub, herbaceous, and bryophyte cover on the establishment of grassland and forest dominants have been observed (Niering and Goodwin, 1962; Webb *et al.*, 1972; Pons, 1989), and it is widely recognized that many small-seeded herbs, trees, and shrubs are incapable of establishment in a closed cover of vegetation.

It can be deduced therefore, that there is a potential for subordinate members of a plant community to act as a filter in selecting between different potential dominants during the early phases of recolonization following a disturbance event. Selection could operate on the basis of variation in the seed reserves of dominants and on the capacity of their seedlings to penetrate a low canopy. The filter might also discriminate between dominants that rely on rapid emergence and those that regenerate by persistent juveniles. Subordinates could also control regenerating dominants through more indirect

mechanisms, such as provision of sites in which seed predation is reduced, or through more complex phenomena such as the maintenance of critical pests, pathogens, herbivores, or mutualists.

Founder Effects of Transients?

If, as suggested earlier in this article, the sources of the transients are seed banks in the soil and the seed rain from the surrounding landscape, it would appear that they are an index of the pool of potential colonizing species at each site. On this basis, a diversity of transients signifies a high probability that, in the event of habitat disturbance or changes in management, there will be a rapid ingress of different plant functional types, some of which may be capable of exploiting the new conditions. An obvious example is the benefit to woodland development where an abandoned grassland already contains a diverse assortment of tree seedlings.

Current losses in biodiversity in Europe and in many other parts of the world are taking place in a complex landscape mosaic that is continuously disturbed by natural events and by urbanization, arable cultivation, forestry, and various forms of grassland management. Ecosystem sustainability depends, in part, on the continuous movement of populations and the reassembly of vegetation types and ecosystems. The extent to which communities and ecosystems are rapidly reconstituted is likely to be related to the reservoir of colonizers, many of which should be detectable prior to disturbance as transient constituents of the existing vegetation. As Egler (1954) recognized, the authors may suspect that the speed and completeness with which ecosystem reassembly occurs will depend on early colonization by appropriate dominants and subordinates; late arrivals will be delayed in their establishment and some may be excluded completely (Keever, 1950; Niering and Goodwin, 1962; Platt, 1975). It is not difficult to envisage how circumstances could then arise whereby efficiently dispersed plant species with “poor fit” to habitat and management conditions could assume dominance with damaging consequences for ecosystem function. There is an urgent need to discover the extent to which failure in the processes of plant dispersal and ecosystem reassembly can be predicted from the decline through time in the density and species richness of transients in plant communities.

Conclusions

The species richness of herbaceous vegetation is controlled by ecosystem processes related to rates of productivity and disturbance; the balance of evidence suggests that richness itself exerts only a minor control on ecosystem processes. However, this does not mean that losses of plant diversity should be ignored. The priority in the next phase of research on declining plant diversity should be to consider its long-term consequences on ecosystem structure and function. Losses in species richness may be associated with less obvious impacts that operate through failures in filter and founder effects. A progressive loss of ecosystem functions may be predicted in

circumstances where vegetation patch dynamics and ecosystem reassembly continue against the background of a declining pool of colonizing propagules. The effects on the recruitment of dominants, rather than the immediate consequences of declining richness *per se*, deserve our curiosity and attention.

Glossary

Economic impact Capacity of weeds to limit productive use of terrestrial environments and the costs associated with their control in both managed and natural areas.

Environmental impact Ability of weeds to displace native fauna and flora, alter key ecosystem functions, and change disturbance regimes.

Introduced plants Species transported by humans to regions outside their natural geographic range.

Invasive weed Introduced plant species that establish self-maintaining populations and spread, with and without human assistance, into new areas where they frustrate human intentions in production and natural landscapes.

Introduction

Human migration, settlement, and trade over the past two centuries have produced a rapid globalization of floras with independent evolutionary histories that were previously kept apart by natural barriers. The scale of movement and mixing of floras in recent years is unprecedented in the earth's history, and very few parts of the world currently retain an exclusively native assemblage of plant species. Hundreds of naturalized plants, no longer dependent on humans for their persistence, occur in most regions and countries, where they form a significant and growing proportion of the wild flora. Over large continental areas the contribution of established introduced plants can reach 23% of the total flora (e.g., Canada), but this is greatly exceeded on many islands where the naturalized flora may outnumber the pool of native species (e.g., Bermuda, Ascension, New Zealand). Despite the many benefits provided by introduced plant species, there is growing concern at the environmental damage and economic costs of naturalized invasive plants in both productive and natural ecosystems. Important negative impacts are created by a small subset, probably less than 0.01% of all introduced species growing in a region, but their control, management, and impact consume significant economic resources, especially of developed countries.

The extent, patterns, and consequences of introduced plant invasions are described in another chapter presented in this volume, "Plant Invasions." This chapter highlights the negative impacts of introduced plant species using case studies of notable invasions, particularly those that have spread into natural areas with serious deleterious consequences for native species and communities. Examples of invasive plant species have been selected on the basis of a well-documented, and therefore relatively recent, spread and impact in natural environments. They are not necessarily the most widespread plant species, or the most aggressive, and some are limited to a few regions or countries. However, they are representative of the pattern and scale of intercontinental transfer of introduced plant species and the types of dramatic impacts these species can have when released into new environments. The examples chosen include a range of plant growth forms, altitudinal and

bioclimatic zones, regions of origin, and modes of negative impact.

For ten introduced invasive plant species, representing algae (*Undaria pinnatifida*), ferns (*Salvinia molesta*), grasses (*Bromus tectorum*, *Spartina alterniflora*), small herbs (*Hieracium pilosella*), large herbs (*Fallopia japonica*), cacti (*Opuntia*), shrubs and small trees (*Lantana camara*, *Mimosa pigra*), and tall trees (*Pinus pinaster*), an account is given of the invasion process; local ecological, cultural, and economic impacts; attempts at control; and likely long-term consequences. Not all invasions are irreversible, and several examples illustrate successful levels of population control, if not eradication.

Notable Examples

Undaria Pinnatifida (Laminariales)

Some of the most pronounced ecological impacts and intractable problems of introduced species invasion involve marine organisms. Both deliberately and inadvertently introduced macroalgae have become invasive in recent decades with the increase in marine farming, transoceanic and coastal shipping, and the discharge of ballast water in and around foreign ports. The Asian laminarian kelp (*Undaria pinnatifida*), native to Japan, Korea, and China, has been introduced and spread since 1970 in other northern hemisphere waters (e.g., England, French Atlantic, and in parts of the Mediterranean near France, Spain, and Italy). More recently (1980s), populations have been discovered in the southern hemisphere (Argentina, Australia, and New Zealand), making it the first large kelp to cross tropical waters successfully. In its native range *Undaria pinnatifida* is widely cultivated as an edible seaweed, and new locations are often viewed positively for their commercial potential. However, the alga is highly invasive, has significant negative conservation impacts on the local native shallow marine fauna and flora, and may be impossible to eradicate.

Native to the north-west Pacific, *Undaria pinnatifida* has an annual, heteromorphic life cycle, with macroscopic sporophytic and microscopic gametophytic stages. The golden

brown, pinnatifid sporophyte, up to 3 m long, grows over autumn and winter, before degenerating in the summer. When growth slows, sporophylls develop as undulating extensions at the base of the stipe and release millions of short-lived (generally less than 2 days) male and female pelagic spores which, following settlement, develop into small gametophytes that may overwinter before producing either eggs or sperm. Fertilization of the female egg cell by male gametes gives rise to the straplike juvenile sporophyte. *Undaria pinnatifida* grows from low water to a depth of 20 m, depending on turbidity and wave exposure, and tolerates sea surface temperatures from 0 to 27 °C. In Japan, it is an important edible seaweed crop and is also cultivated extensively to feed juvenile abalone (*Haliotis* spp.).

Undaria pinnatifida first appeared outside its native range in 1971 in a lagoon on the south coast of France, in the Mediterranean Sea. The source is thought to have been contaminated oyster spat translocated from the Pacific. It has subsequently spread along northern parts of the Mediterranean from Spain to Italy. In 1983 *Undaria pinnatifida* was deliberately introduced to the French Atlantic for experimental aquaculture trials, on the basis that sea temperatures would be too cool (<14 °C) for the release of zoospores. This assumption was proven incorrect when ecological surveys during the 1990s revealed natural establishment at five of the nine cultivation sites, some now abandoned, with several new populations up to 20 km away from nearest putative sources. *Undaria pinnatifida* appeared on the south coast of England in 1994, the population mostly likely deriving from microscopic gametophytes or juvenile sporophytes attached to boats arriving from Brittany.

Spread of *Undaria pinnatifida* into the southern hemisphere has been very recent, beginning in the 1980s, and accidental, presumably from plants attached to ships or in seawater ballast. *Undaria pinnatifida* was first discovered in New Zealand in 1987, and has subsequently spread, mainly via sporophytes and gametophytes attached to hulls of boats, to more than ten localities, up to 1000 km apart (Figure 1). Soon after (1988) the kelp was discovered in Tasmania, in and around several major ports, and was recently (1996) reported from coastal

Figure 1 Intertidal kelp forests of *Undaria pinnatifida* recently established along parts of the eastern South Island, New Zealand. Photo: National Institute of Water and Atmospheric Research.

waters on the Australian mainland. The first South American population was discovered in Argentina in 1992.

While fouling boats and underwater structures is of nuisance value, the full ecological impact of *Undaria pinnatifida* in these new habitats is hard to predict, as the species is a very recent invader in foreign waters, is mostly confined to highly modified habitats in harbors, and initially preferentially colonizes clean, artificial surfaces. Investigations in the Atlantic suggest that *Undaria pinnatifida* is preempted on denuded rocky substrates by several local native annual and perennial kelps. Because of this competition, it may eventually be restricted along the coast in northern France to the low tide zone. In Tasmania, following disturbance and dieback of the native kelp due to ocean warming, *Undaria pinnatifida* displaces *Macrocystis* kelp forests and dominates subtidal urchin barrens due to its high fecundity and fast growth rate. However, it is less successful against native seaweeds on exposed coasts with slow currents. In New Zealand, *Undaria pinnatifida* reduces habitat for native marine grazers by smothering coralline algal surfaces favored for larval settlement of the animals. The region has a depauperate flora of annual and early successional seaweeds, and *Undaria pinnatifida* has few effective competitors on fresh surfaces created by storms and echinoid grazing. Frequent wave induced substrate disturbances could consolidate the dominance of *Undaria pinnatifida* in many shallow marine habitats.

While the transoceanic and local spread of *Undaria pinnatifida* has been dependent on human activity, the alga has several attributes that make it an aggressive competitor in shallow marine habitats. Sporophytes densely colonize any unvegetated surfaces, and huge populations can establish within a year on boats, wharf piles, mooring buoys, and on breakwater or reclamation debris. These can provide multiple sources for short- and long-distance dispersal. Importantly, *Undaria pinnatifida* occurring outside its native range can, in warmer waters, produce several generations of sporophytes each year, while local kelp species are reproductively dormant for part of the year.

The negative effects of *Undaria pinnatifida* on marine aquiculture and numerous algal communities are potentially enormous, and most countries where the species has established are pursuing some form of control. However, the large reproductive potential and cryptic dispersal phases of Asian kelp, together with the partial obscurity provided by the marine environment, combine to make detection and control of *Undaria pinnatifida* almost impossible. Reducing the rate of spread of *Undaria pinnatifida* may be practicable with improved ship hygiene practices in ports and the strict control of aquaculture ventures. Eradication of small populations, using direct removal of sporophytes by divers, or sterilization of mariculture equipment, may also be possible where pioneer plants are restricted to artificial structures (e.g., mooring lines), but this is unlikely to be achieved where *Undaria pinnatifida* has established in harbors and along exposed coasts.

***Salvinia Molesta* (Salviniaceae)**

Ferns are rarely successful weeds in natural ecosystems, but a notable exception is *Salvinia molesta* (kariba weed, African

pyle, Australian azolla, water fern, giant azolla), a free-floating perennial aquatic fern native to tropical and subtropical areas of South America. In the later part of the 20th century it has been spread worldwide, becoming invasive in fresh waters in warm-temperate to tropical areas, and causing major disruptions to the utilization of important water resources.

Only formally described in 1972, *Salvinia molesta* is a sterile pentaploid, probably of natural hybrid origin. Native to parts of Brazil and Argentina, it grows there in lagoons, swamps, and river margins with still or slow-moving freshwater, in a diverse community of floating and emergent plant species. In these situations *Salvinia molesta* occurs at low densities, does not form extensive mats, and is rarely invasive.

Morphologically the species is quite plastic, exhibiting several distinctive forms. At each node *Salvinia molesta* supports submerged (which function as roots) and floating leaves. The size, shape, and density of the foliage changes depending on environmental conditions (temperature and nutrient concentrations) and growth phase. When *Salvinia molesta* first establishes, usually in calm, sheltered waters, the plants are small (20 mm), with oval, flat floating leaves. With time, leaves become rounded and larger, and in the final mat-forming stage are folded, crowded, and between 50 and 60 mm across. *Salvinia molesta* is efficient at accumulating and reutilizing nutrients such as nitrogen.

Salvinia molesta has become widely distributed through aquarium and horticultural industries and is now naturalized in Australia (Figure 2), Africa, Madagascar, India, Sri Lanka, Southeast Asia, Philippines, Indonesia, Papua New Guinea, Fiji, and New Zealand. Dispersal between water systems is also

invariably by human activities (e.g., boats, aquaria), but spread within and between interconnected water bodies is assisted by wind and water movement of vegetative fragments. Outside its native environment, *Salvinia molesta* shows phenomenal growth rates, via the expansion of auxiliary buds at stem nodes. Under optimum conditions (30 °C and high nitrogen levels), plant area can double every 8 days and biomass every 2.2 days. In Australia total floating biomass values of 1600 g⁻¹ m⁻² dry weight, or 400 t ha⁻¹ fresh weight, have been recorded. Frequently *Salvinia molesta* forms mats 1 m deep across extensive waterways.

During the 1970s and 1980s, *Salvinia molesta* was seen as potentially one of the worst invasive weeds globally, with major ecological and socioeconomic impacts. The basis for this concern is well illustrated by accounts of the species invasion in Papua New Guinea. In the early 1970s *Salvinia molesta* became established in the Sepik River flood plain, and within a decade covered 250 km² of water surface. The weed impeded water transport, preventing fishing, trade between villages, and access to medical and educational facilities. Fresh water for humans, stock, and wildlife became restricted, and *Salvinia molesta* mats proved suitable habitats for insect vectors of serious human diseases such as malaria. Similarly, in Zimbabwe, *Salvinia* threatened utilization of Lake Kariba, a massive impoundment on the Zambezi River created in the 1950s for hydroelectricity generation, commercial fishing, recreation, and transport. Within 15 years of the scheme being completed, mats of *Salvinia molesta* were limiting human access, decreasing fish populations, and modifying nutrient regimes. Elsewhere, *Salvinia molesta* has also invaded rice fields, blocked irrigation ditches, eutrophied small water bodies, and smothered emergent, floating, and submerged indigenous aquatic plants. A severe reduction in light and dissolved oxygen, together with an increase in carbon dioxide and hydrogen sulphide, have had a drastic impact on most benthic biota.

The management and eradication of *Salvinia molesta* focused initially on mechanical removal and the use of chemical herbicides, and these were occasionally effective, especially where original populations were small or isolated. However, repeated treatment was required to prevent the rapid recovery of the plants, and the techniques used were expensive and occasionally environmentally damaging. Since 1980, biological control of *Salvinia molesta*, using a foliage- and stem-feeding weevil (*Cyrtobagus salviniae*—Curculionidae) from its native habitat, has been outstandingly successful in suppressing populations and achieving control in many countries (e.g., parts of Australia, Papua New Guinea, Fiji, South Africa). For example, the weevil had reduced the cover of *Salvinia molesta* on two 16 ha dams in Zimbabwe from over 90% to under 2% in less than two years. Similarly impressive results were achieved at a much larger scale in the Sepik River. Following the weevils' introduction, large mats of *Salvinia molesta* are typically reduced to sparse plants around the margins of water ways, interspersed with other aquatic plant species of the region. After the collapse of the *Salvinia* plants, weevil numbers also decline but appear to remain at densities sufficient to keep the weed in check. The global benefit of this successful example of biological control has been estimated to surpass \$A200 million.

Figure 2 Attempted mechanical removal of extensive mats of *Salvinia molesta* blocking large waterways in Queensland, Australia. Photo: Queensland Department of Natural Resources.

Bromus Tectorum (Poaceae)

The development of rangelands for pastoral use, through stock grazing, fire, and the deliberate and incidental introduction of new plant pasture species, has involved some of the most extensive modifications to natural ecosystems ever undertaken by humans. In the semi-arid intermontane west of North America more than 400,000 km² of native sagebrush-steppe communities have been penetrated or displaced this century by *Bromus tectorum* (cheatgrass, downy brome, downy chess, drooping brome), a winter annual grass native to arid Europe and Central Asia. The dominance of this species has resulted in changes in land use, increases in erosion potential, reductions in native biodiversity, and alterations to the major disturbance regimes over large areas. *Bromus tectorum* is considered to be the most significant plant invasion in North America.

The native habitat of *Bromus tectorum* is centered on dry continental climates. Commonly associated with human activities, it occurs in grazed and ungrazed grasslands, among crops, and along roadsides. Flowers are hermaphroditic and self-fertile, and populations survive the dry summer period as seed. It characteristically germinates in autumn, estivates during the coldest parts of winter, and can grow rapidly, to around 50 cm tall in spring, when it flowers. The plants die back during the hot, largely rainless, summer. Seeds can be widely dispersed via animals, as they have long awns that are frequently embedded in fur or wool. Transfer by humans is usually accidental as a seed contaminant and among farm machinery. *Bromus tectorum* is now found in temperate East Asia, North and South America, and Australasia.

Prior to European settlement, the natural vegetation of the Great Basin area contained perennial cespitose grass-dominated steppes, the grasses (*Agropyron*, *Festuca*, *Stipa*, *Poa*) and forbs on mesic sites, giving way to shrubs (*Artemisia*, *Chrysothamnus*) in drier areas. The accidental introduction of *Bromus tectorum* into the intermontane region of the Pacific Northwest late in the 19th century, and several deliberate attempts to establish it as an alternative pasture species, coincided with large-scale domestic grazing by cattle, sheep, and horses. Because of the low abundance of large ungulates (bison and deer) during the Holocene, the original grasses and shrubs were generally poorly adapted to grazing ruminants. The flora also lacked aggressive colonizing annuals that could reclaim sites following disturbance. Burning by early settlers to remove shrubs and improve stock access further depleted the vegetation. Initially a weed of cultivated fields and roadsides, *Bromus tectorum* rapidly spread via wind and animal dispersal, and in seed lots, into overgrazed and vulnerable ungrazed native communities, becoming a widespread and dominant weed in the 1930s and reaching its current distribution in North America by the 1950s. Spread since then continues but at a slower rate.

The expansion of *Bromus tectorum* has caused multiple changes in natural ecosystems, largely through its impact on the grass/fire cycle. Accumulation of its highly flammable dry litter following spring growth, has resulted in an increase in the frequency of natural lightning-induced summer fires from 2 to more than 20 per century. Frequent burning has killed native shrubs and depleted the recruitment of perennial

Figure 3 Extensive arid steppe in Washington State, USA, dominated by *Bromus tectorum* which, following fire and grazing, displaces native shrubs (foreground) and grasses. Photo: Richard Mack.

grasses. In contrast, *Bromus tectorum* benefits from fire, due to its large seed bank, prodigious and prolonged germination, rapid seedling growth, and heavy annual flowering. It is therefore able to preempt the recolonization of burned areas by native species already weakened by regular fires. Greater intensity and frequency of burning following *Bromus* invasion reduce plant cover, giving rise to erosion-prone landscapes. *Bromus tectorum* provides poor-quality herbage for stock, and its dominance has resulted in a decline in rangeland quality (Figure 3).

The outcome for conservation and pastoralism of the transformation, in less than half a century, of natural semiarid steppe dominated by shrubs and perennial grasslands, to communities predominantly of introduced annual grasses, remains uncertain. *Bromus tectorum* appears uncontrollable under extensive management systems. It is still spreading into more isolated areas of the Great Basin and into the Great Plains region of the United States.

Hieracium Pilosella (Asteraceae)

Numerous flat-weeds (rosette species) have accompanied European colonization of temperate regions around the world. Most of these plants are small, shortlived (2 years), dependent on human disturbance for local persistence, and generally inconsequential as weeds outside intensively managed systems. *Hieracium pilosella* (mouse-ear hawkweed), a perennial, stoloniferous, mat-forming daisy native to Europe, has a worldwide distribution in temperate regions and was generally considered to be relatively benign until it started to invade grasslands in New Zealand in the 1950s. Currently it occupies about 1 million ha of montane-subalpine short tussock (*Festuca novae-zelandiae*) grassland in subhumid and humid zones and is seen as the greatest threat to the conservation and long-term pastoral use of native grasslands. Key ecological factors responsible for the spread of *Hieracium pilosella*, and management options for its control, are controversial, and highlight the problems of large-scale weed management in nonforest ecosystems.

Native to Europe, *Hieracium pilosella* is a prostrate rosette-forming herb that reproduces vegetatively via stolons, which are initiated following flowering. Seed can be produced by both sexual and apomictic processes. In addition, hybridization and polyploidy are common and give rise to complicated population structures. Rosettes produce an erect short scape, which supports a solitary lemon-yellow flower that produces abundant small wind-dispersed achenes. In its native range the species is characteristic of disturbed dry habitats, most often grazed pastures, wastelands, and outcrops, particularly on calcareous soils below 1000 m above sea level.

Introduced into New Zealand in the middle of the 19th century, most likely as a seed contaminant, *Hieracium pilosella* remained locally restricted and largely insignificant for more than a century. The invasive phase of *Hieracium pilosella* became obvious during the 1960s, initially in the semiarid intermontane basins in the South Island, where the species became dominant in grazed *Festuca-Poa* grassland induced by pastoralism. Following burning of the original native forest and woodland during early Polynesian settlement, approximately 600 to 1000 years ago, tall tussock *Chionochloa* grassland and shrub land extended onto these areas. Early European pastoralists, in the first few decades of the 19th century, increased fire frequency and brought in sheep and cattle which, assisted by periodic eruptions of introduced rabbit populations, destroyed dominance by the tall cespitose grass species. The decline in plant cover and increasing bare ground provided numerous sites for invasive grazing-tolerant plant species. Foremost amongst these has been *Hieracium pilosella*, which slowly occupied the most depleted areas (those with 500 to 1200 mm rainfall) over about 50 years, becoming widespread and dominant in the 1970s when it began to extend into subalpine tall tussock grassland. In the 1990s *Hieracium pilosella* became the most widespread and significant introduced weed in native grasslands (Figure 4), accompanied in parts of its range by the introduced congeners *Hieracium praealtum* and *Hieracium lepidulum*.

During its colonizing phase *Hieracium pilosella* forms distinctive circular patches that gradually coalesce to cover large areas. In eastern parts of the South Island, instantaneous rates of increase of approximately 8% per year have been recorded,

Figure 4 Mass flowering of *Hieracium pilosella* in *Festuca-Poa* short tussock grassland, eastern South Island, New Zealand. Photo: Stan van Uden.

with local cover values of *Hieracium pilosella* exceeding 50%. Much of this local expansion is attributable to vegetative reproduction, with seedlings being rare. *Hieracium pilosella* smothers and displaces small native herbs and grasses and restricts the survival of productive pasture grasses and legumes. Soil changes beneath *Hieracium pilosella*, especially increasing rates of acidification, also limit the growth of introduced legumes.

There is little doubt that human activities, especially repeated fire, and the grazing of domestic and feral animals, have increased the vulnerability of indigenous grasslands to invasion by introduced plant species. However, some relatively unmodified native habitats, especially in subalpine areas, on braided river beds, in semiarid environments, and on unstable hillslopes, may also be vulnerable due to tectonically induced natural erosion maintaining bare ground. *Hieracium pilosella* possesses several attributes that enable it to out-compete many low-growing native grass and herb plant species, especially in drier regions. These include rapid growth, vigorous vegetative reproduction, drought-tolerance, and grazing resistance. Furthermore, *Hieracium pilosella* is more efficient than native plant species in utilizing seasonal pulses of nutrients and water. The widespread aerial application of superphosphate fertilizer in upland areas may also have contributed to the spread of *Hieracium pilosella* in recent decades. New Zealand plants of *Hieracium pilosella* are entirely polyploid with high levels of genetic variation enabling the rapid evolution of innovative genotypes for colonizing new habitats.

The future of *Hieracium pilosella* in indigenous grasslands probably depends on land-use goals. In tall-tussock grassland, in the absence of mammalian grazing, natural vegetation cover and successional processes eventually leave *Hieracium pilosella* restricted to marginal habitats. However, the outlook for induced short-tussock grassland, with or without stock or feral animal grazers, is less clear, and *Hieracium pilosella* may well monopolize these communities in the longterm, or at least until succeeded by shrubs. Active management in areas under extensive pastoralism involves grazing to reduce flowering and applications of fertilizer to improve the competitive ability of associated grasses and legumes. A biological control program in New Zealand is currently underway, and two agents collected from Europe have been utilized: a pathogenic rust fungus (*Puccinia piloselloidarum* var. *hieracii*) and a gall wasp (*Aulacidea subterminalis*), which forms galls on stolons.

Spartina Alterniflora (Poaceae)

Estuarine habitats, characterized by waterlogged soils and regular saltwater incursions, provide a severe environment for plants and usually support a sparse halophytic flora. One kind of plant that is able to form dense monospecific stands in these environments is the grass *Spartina* (cordgrass), especially *Spartina alterniflora* and its derivatives, which have spread in estuaries in many subtropical and temperate regions of the world. The invasion of *Spartina alterniflora* is significant because of the rapid evolutionary process involved and the growing recognition of the biodiversity values of estuarine areas.

Spartina species are perennial, deep-rooted (30 cm), rhizomatous, sward-forming erect grasses that mostly occupy low- to midtidal mudflats. They are well adapted physiologically to tolerate saline conditions with special salt excretion, dilution, and restriction mechanisms. A high water-use efficiency, due to their C_4 photosynthetic system, and the unusual ability to maintain higher rates of photosynthesis than other C_4 and many C_3 species under cool temperate conditions (5–10 °C), increases their environmental range.

The native geographic distribution of the genus centers on the east coast of North and South America, with fewer species on the west coast of North America, Europe, and north Africa. *Spartina alterniflora*, native to the Atlantic coast of North America, was accidentally introduced to the United Kingdom early in the 19th century, and produced rare hybrids with the local congener *Spartina maritima*, which is restricted to western Europe and Africa. The male sterile F_1 hybrid *Spartina* $\times$ *townsendii* subsequently produced, via doubling of chromosomes, a new fertile species *Spartina anglica*. It quickly became apparent that *Spartina townsendii*, and particularly *Spartina anglica*, were markedly more invasive than either of the parent species. Estuarine habitats in southern England were transformed from exposed mudflats into tall-grass meadows. In less than a century *Spartina anglica*, via seed dispersal, clonal spread, and human plantings, covered approximately 10,000 ha of intertidal salt marsh along the coast of Britain.

Early this century, estuarine stabilization to maintain commercial waterways and reclamation for industrial and agricultural development were seen as important goals of coastal management. Experience in the United Kingdom resulted in *Spartina alterniflora* and its derivatives (*Spartina* $\times$ *townsendii*, *Spartina anglica*) being widely planted in parts of North America, in regions occupied by native *Spartina* species, and in areas well outside its native range (e.g., Australia, and New Zealand) where they were similarly successful, especially *Spartina anglica*. The heightened competitive vigor and environmental range of *Spartina anglica* appears to derive from a greater genetic heterozygosity, due to hybridization and polyploidy, and expanded phenotypic plasticity. Spreading *Spartina* species appear to have fewer insect and avian herbivores in their new ranges.

Invasive *Spartina* species induce major geomorphological changes in tidal habitats by enhancing rates of sediment accumulation. Sediment accretion rates of up to 17 cm yr⁻¹ (average 5–10 cm) have been recorded within the tall grass sward, and in southern England *Spartina* caused elevation of mudflat surfaces by 1.8 m in 37 years. Declining tidal influence, and the accumulation of biomass (dry weight up to 7500 kg ha⁻¹), transforms salt marsh areas into nonestuarine ecosystems. Impacts on biodiversity are no less dramatic. At the pioneer phase, establishment via seed or planting produces circular clumps that expand at rates of between 3 and 7 m yr⁻¹, eventually coalescing to form extensive meadows on sand and mud substrates in the low- to midtidal range (Figure 5). *Spartina anglica* physically displaces many native indigenous low-growing halophytes (e.g., *Selliera*, *Salicornia*, *Schoenus*, *Puccinellia*) and modifies habitats formerly occupied by a range of bird, fish, and invertebrate species. In southern New Zealand, the loss of fish and other food sources in estuaries colonized by *Spartina anglica* threatens the persistence of 34 species of foraging shorebirds in these habitats.

Figure 5 Colonizing patches of *Spartina alterniflora* on mudflats at Wilapa Bay, Washington, USA. Photo: Glen Miller.

The hybridization of native and introduced *Spartina* species during the 19th century in the United Kingdom is presently occurring in western North America, where the recently established *Spartina alterniflora* (introduced) is genetically assimilating the common *Spartina foliosa* (native) through introgressive hybridization. Abundant *Spartina alterniflora* pollen improves seed set in *Spartina foliosa*, producing fertile hybrids that also cross with the native species. Locally, the introduced *Spartina* species and progeny could readily displace the native species and colonize lower reaches of the mudflats, currently beyond the environmental tolerance of the *Spartina foliosa*.

Because of growing appreciation of the biological values of estuaries, new plantings of *Spartina alterniflora* have largely ceased, and the species is now considered a serious weed. Extirpation of existing *Spartina* meadows has, however, been difficult, but containment and the removal of outliers has been achieved using systemic herbicides.

Opuntia (Cactaceae)

Cacti are prized as ornamentals for their novel form, spectacular flowers, edible parts, and medicinal uses. *Opuntia* (prickly pear) a genus of about 90 species native to North and South America, has been distributed globally over the past two centuries. Sixty species have become naturalized, and at least 15 are considered major weeds. *Opuntia* species provide some of the earliest and most spectacular examples of invasive plants in dry environments and the effectiveness of insects as biological control agents. In the major centers of *Opuntia* invasion (Australia, South Africa, and India), several species have displaced horticultural crops, reduced the grazing potential of rangelands, and threatened the conservation values of native grasslands, scrublands, and woodlands. Eradication may be unattainable, but some invasive *Opuntia* species are now at low population densities, while others are continuing to spread.

Opuntia species are fast-growing perennial succulents with thickened, often flattened, segmented cladodes, usually supporting spines. Most *Opuntia* will regenerate from seed, cladode fragments, and underground tubers. Ranging in size from

low-growing shrubs to small trees, the species characteristically occupy dry habitats with seasonal water deficits. As with all cacti, *Opuntia* species have a distinctive photosynthetic system (crassulacean acid metabolism or CAM), which enables them to fix carbon at night when evaporative stress is reduced, as well as during the day, if adequate moisture is available. A high water-use efficiency, coupled with a large internal water-holding capacity and the ability to restrict water loss by tightly shutting off stomata, enhance drought tolerance. In North and South America *Opuntia* species are usually sparse and restricted regionally, and several are considered threatened in the wild. The major invasive weed species come from a range of native regions: *Opuntia stricta* (common or erect prickly pear) eastern North America, West Indies and adjacent South America; *Opuntia aurantiaca* (tiger pear, jointed cactus) temperate South America; *Opuntia ficus-indica* (sweet prickly pear, Indian fig) Central America; and *Opuntia vulgaris* (drooping prickly pear, Barbary fig) eastern South America.

Initially *Opuntia* species were distributed outside the New World as ornamental plants, but a range of uses rapidly emerged, especially as stock fodder, hedges, and as fruits or vegetables. A novel use was the production of carminic acid, a commercially important red dye, derived from the crushing of dried cochineal beetles fed a diet of cacti. *Opuntia* can provide an important source of food and income for local communities, and attempted extirpation is not universally accepted.

Introduced into Australia in the early 19th century, *Opuntia stricta* had by 1925 infested more than 25 million ha of eastern Australia and was spreading at the rate of 100 ha per hour, aided by the dissemination of vegetative and seed material by floods, humans, and feral and wild animals. Areas most susceptible were pastoral and arable land cleared amongst *Acacia* and *Casuarina* woodland, although the cacti also penetrated the woodland understorey. The Australian flora has few native succulents, and none with the environmental tolerance of *Opuntia*. Approximately 10 years after initial establishment at a site, ground cover became dominated by impenetrable thickets of *Opuntia* reaching densities of 16,000 plants and a biomass of 250,000 kg, per hectare. The weed frustrated the farming ambitions of European settlers and caused the ruin of early rural economies.

Opuntia ficus-indica, a tall shrub, was established in southern Africa at least 250 years ago. By the early 20th century, infestations occupied 900,000 ha, mainly in the Eastern Cape region, occupying grassland, succulentkaroo, and the savanna biome (Figure 6). *Opuntia aurantiaca*, a low-growing species, which may be of hybrid origin, was introduced much later (early 19th century), spreading originally from garden plantings around Cape Town. A total infested area of about 400 ha in the 1890s has grown this century to around 830,000 ha, mainly in eastern parts of South Africa. It is replacing important pastoral plants in grasslands and savanna, injuring domestic and feral animals, and degrading natural rangelands. A single cladode can produce up to 145 new cladodes over a 200-day growing period, and the potential for vegetative spread is enormous. Currently *Opuntia aurantiaca* is considered to be South Africa's most expensive weed. *Opuntia vulgaris* has also been an important weed in the latter part of the twentieth century, mainly in western coastal areas.

Figure 6 *Opuntia ficus-indica* invading rangeland in the Eastern Cape Province of South Africa. Photo: John Hoffmann.

In Australia and South Africa, the control of *Opuntia* assumed top priority for land management agencies early in the 20th century, when various herbicidal and mechanical methods were attempted. Poisoning, using a combination of arsenic pentoxide and sulfuric acid, and mechanical cutting were successfully used to control small infestations of *Opuntia* in open lands but were very expensive and achieved little at a regional scale. However, spectacular success has been achieved using plant-sucking cochineal insects *Dactylopius* species and the cladode-eating larva of the moth *Cactoblastis cactorum*. Indications of the potential of insects as biocontrol agents first appeared in 1795, when the accidental introduction of *Dactylopius ceylonicus* resulted in widespread death of *Opuntia vulgaris* in India. Subsequently, deliberate introductions of several *Dactylopius* species have drastically reduced *Opuntia* weed infestations in southern Africa, and *Cactoblastis* has been similarly used to diminish population densities of *Opuntia stricta* in Australia. Overall, biological control agents have lowered population densities of *Opuntia* by 90%, especially in drier climates. *Opuntia* remains a widespread and invasive weed in these countries, but the economic impact on agricultural land uses has diminished hugely, especially in Australia.

Fallopia Japonica (Polygonaceae)

The human passion for gardens increases biodiversity in urban areas, often creating large source populations, which initiate the effective dispersal of introduced plants into adjoining landscapes. One garden ornamental that has become an invasive weed is *Fallopia japonica* (Asiatic knotweed), a large perennial herb native to the Far East. In the 20th century the species has infiltrated much of central and western Europe, North America, and several southern temperate countries, where it excludes native plant species in artificial and highly disturbed habitats, riparian areas, and in open woodlands. In the United Kingdom, *Fallopia japonica* is presently the tallest and most aggressive common herbaceous species.

Fallopia japonica is a rhizomatous, clump-forming, perennial native to China, Japan, Korea, and Taiwan. In these countries it is an early successional species, growing to less

than 2 m tall, colonizing volcanic debris and disturbed riparian habitats, under a range of edaphic conditions, from lowland to subalpine. *Fallopia japonica* establishes on new sites by seed in its native range and persists to develop a large biomass (12 tonnes ha⁻¹), deep litter layer, and a rhizome system that extends for up to 20 m beyond the shoots.

Taken from Japan to the United Kingdom in 1825, for planting in gardens, *Fallopia japonica* was subsequently established in other northern (e.g., North America) and southern hemisphere (e.g., New Zealand) countries late in the 19th century. Although mostly found on heavily modified and disturbed sites within urban environments, it has also spread in natural habitats, especially along waterways. In the United Kingdom it is presently found in over half the 10-km grid squares, being most abundant in southern and western regions (Figure 7). In Wales, for example, *Fallopia japonica* occupies 84% of river systems with average flow rates greater than 2.3 m³ s⁻¹. In North America it has become naturalized in most mesic western coastal regions, north to Alaska, all of the northeastern United States, and parts of central and southern United States. In western Pennsylvania, stands extending for hundreds of hectares cover wetlands, stream sides, and adjoining hill slopes.

Around waterways, *Fallopia japonica* is capable of forming dense thickets up to 500 m across, overtopping and supplanting native herbs, shrubs, and small trees; impeding water runoff and increasing flooding, and modifying nutrient availability and cycling patterns through sequestration in a large standing biomass. Early emergence and fast growth of new shoots and flowering stems, usually completed before midsummer, create a dense overstory, and this, together with prodigious annual litter production, restricts the presence of

other species, except where regular flooding removes surface litter, and the shade from tall trees reduces its vigor.

In its native range, *Fallopia japonica* bears female and hermaphrodite flowers on separate individuals. Elsewhere the species is male-infertile and, although seeds are produced from hybridization with other introduced congeners, spread via successful sexual reproduction is rare. However, spread of rhizome fragments is extremely potent, and viable plants can establish from pieces as small as 7 g, and from burial at depths of up to 1 m. Stem fragments are also able to produce new shoots. In most instances vegetative dispersal is achieved by water currents and the movement by humans of soil and gravel contaminated with rhizome pieces.

The current geographic range in Europe extends north to 63°N and is broadly correlated with degree-days, absolute minimum temperatures (> -30.2 °C), and annual rainfall (> 500 mm). The shoots are vulnerable to late frost and summer droughts, and these factors may constrain the large-scale distribution of *Fallopia japonica*, especially in continental climates. Tolerant of a broad range of soil conditions, *Fallopia japonica* is strongly light-demanding and rarely enters forests.

Once established, *Fallopia japonica* is difficult to remove. In Europe and North America young shoots of *Fallopia japonica* are occasionally eaten by stock, and this may reduce the development of clumps and slow the rate of spread. Where accessible, regular cutting or spraying with herbicides can achieve control, but follow-up treatments over several years are needed to weaken and eventually kill the rhizomes.

Lantana Camara (Verbanaceae)

International trading in plants and the intensive search for novel cultivars for horticulture has produced new hybrids with high invasive capacity and given them near-global distributions and access to a great range of habitats. *Lantana camara* (lantana, white sage, wild sage, tick berry), a perennial shrub with brightly colored flowers, was taken from Brazil to Europe in the middle of the 17th century as a hothouse plant. During the next several hundred years, extensive hybridization and propagation of different varieties, augmented by new collections from the native region, produced a proliferation of forms. Commonly grown in gardens, *Lantana camara* has now become a major weed worldwide in tropical, subtropical, and warm temperate regions. It invades pastures, plantation crops, and a range of disturbed-open natural and modified scrubland, woodland, and forest communities, displacing the indigenous biota and limiting public access and use. Because of its broad distribution, invasive ability in both agricultural and natural ecosystems, and local persistence, *Lantana camara* is considered one of the world's top ten weeds.

Lantana camara is an aromatic shrub with distinctive four-angled stems, often armed with recurved prickles. It has multicolored, insect pollinated, bisexual, potentially self-fertile flowers that produce purplish-black drupes by assorted sexual, semisexual, and apomictic mechanisms. Native to parts of Central and South America, *Lantana camara* is actually a complex of species and varietal forms of mixed hybrid origin. It is a genetically diverse group, with ploidy levels ranging from diploid to hexaploid. The most weedy variety

Figure 7 Complete cover of *Fallopia japonica* in urban wasteland, Swansea Valley, United Kingdom. Photo: Simon Fowler.

(*Lantana camara* var. *aculeata*) is tetraploid. The growth form (e.g., ground creeper, prostrate shrub, tall shrub, liane) of *Lantana camara* is equally plastic, varying with light and soil conditions, but with support plants can reach 15 m into the canopy.

The species currently grows in many countries between 45° N and 45° S, but appears to be limited to minimum mean monthly temperatures above 5 °C, rainfall in excess of 650 mm per annum, and nonsaline soils. It is a serious weed in the Caribbean, in eastern Africa, South Africa, India, Madagascar, Australia, and the Pacific Islands.

Lantana camara is an important weed of plantation crops. In India, it has taken over land used for tea and sugarcane production, causing the displacement of whole villages, and in other countries it is a major nuisance in cotton, coffee, coconut, oil palm, bananas, pineapple, rubber, and rice crops. In continental countries such as Australia, India, and South Africa, it is natural grasslands that have been most extensively modified by *Lantana camara*. In eastern Australia alone approximately 4 million ha of grassland have become covered, eliminating both indigenous species and pastoral agriculture. Remnants of semideciduous forest are also invaded via edges and natural and human disturbances of the canopy. In South Africa, 44% of 1-km grid squares were infected with *Lantana camara* in a survey of 14 major forest reserves.

The spread of *Lantana camara* on remote volcanic islands with distinctive biotas has been of international concern and has usually been associated with European settlement and vegetation clearance via fire, roads, and grazing mammals (Figure 8). On the Galapagos Islands, famous for their biodiversity and role in the origin of evolutionary theory, *Lantana camara* endangers both rare plants and animals. It is considered to have caused the extinction of one plant species and threatens the demise of at least eight others. The weed is also closing in on the last remaining colony of the dark-rumped petrel (*Pterodroma phaeopygia*), and will, if not managed, seal off bird access to burrows. In the Indian Ocean, *Lantana camara* is one of several shrub-creepers invading and depleting native forests on La Réunion Island. Initially colonizing natural gaps, it subsequently ascends to smother and weaken canopy trees, making them more susceptible to damage during cyclones. It

Figure 8 Flowering *Lantana camara*, a major threat to indigenous biodiversity on oceanic islands. Photo: Simon Fowler.

is predicted that *Lantana camara* will increase dominance with successive cyclones and eventually displace the forest cover. Thirteen years after its introduction to the Hawaiian Islands in 1858, *Lantana camara* had become naturalized on all the islands and is considered to be the number one problem plant. It currently occupies more than 160,000 ha, mainly in coastal and lowland areas, covering cropland, shrub land, savanna, and destroying opened up forest.

Apart from a broad environmental tolerance, the species has numerous traits that facilitate its dispersal, penetration, dominance, and persistence in different ecosystems. In tropical climates flowers and seeds may be produced all year, and fruits are eaten and widely dispersed by a range of birds and mammals, including some similarly invasive introduced species (e.g., Indian mynah, *Acridotheres tristis*). Most disturbed vegetation types are vulnerable to invasion by *Lantana camara*. Grassland, shrub land, and woodlands, from coastal to mountain areas, are transformed into dense stands of *Lantana camara* as it smothers herbs and other shrubs. Continuous closed forest is less susceptible as *Lantana* has greatly reduced vigor in deep shade. However, plants can penetrate forest from around the margins, readily establish in gaps created by natural treefall, and prevent the regeneration of canopy trees. Plants are flammable, even when green, and facilitate the spread of forest fires. Foliage and seeds are toxic for many grazing mammals and the thick, prickly stands of *Lantana camara* are virtually impenetrable. Thickets also provide habitats for vermin and disease vectors (e.g., tsetse fly).

Techniques for effectively controlling *Lantana camara* are slowly emerging, although most depend on the rapid establishment of vigorous crops or pastures following initial suppression of the weed. Mechanical methods are generally less successful, because *Lantana camara* generally resprouts from plant fragments, basal shoots, and roots after fire, cutting, or digging. Herbicides, especially those based on phenoxy or benzoic acid or pyridine, have variable success depending on climate, season, and growth form. Biological control appears to be sometimes effective, especially in drier areas, utilizing a mixture of seed- and foliage-feeding insects.

Mimosa Pigra (Fabaceae)

Nitrogen-fixing shrub legumes provide some of the most aggressive and disruptive invasive plant species in many parts of the world. One of the most spectacular plant invasions this century has been the spread of *Mimosa pigra* (giant sensitive plant, zaraz, dormilona) in tropical wetlands in parts of Asia, Africa, and Australia. In less than a century, 450 sq km of natural habitat associated with flood plain areas and rivers around Darwin, northern Australia, have been transformed into dense stands of *Mimosa* (Figure 9). The species endangers the conservation and use of natural wetland ecosystems in tropical regions worldwide.

Mimosa pigra is a prickly shrub native to Central and South America where it forms shrub lands up to 5 m tall in areas with seasonally high humidity. Its current pantropical distribution reflects human movement of plants since the 16th century, most likely because of fascination with the touch-sensitive rapid folding of the foliage. *Mimosa pigra* has

Figure 9 Dense stands of *Mimosa pigra* during the wet season, northern Australia. Photo: CSIRO Entomology.

naturalized beyond its native range in Asia (e.g., Thailand, Malaysia), America (e.g., Costa Rica, Brazil), Africa (e.g., Namibia, South Africa), and Oceania (e.g., Australia, New Guinea). Climatically, *Mimosa pigra* favors the seasonally dry tropical zone, with an annual rainfall of between 750 and 2250 mm, mean annual temperature above 17 °C, and mild winters.

Characteristics that make *Mimosa* such an aggressive invasive plant species include rapid growth rate (10 mm per day), rapid maturation (germination to first flowering within 6 months), potentially autogamous, abundant seed production (9000 seeds per m² annually), a large, long-lived (> 10 years) seed bank in soil, and an effective dispersal system (flotation of clusters of capsules and via attachment to animals). Spines on the stem and leaf rachis deter most mammalian grazers and, outside its native range, there appear to be few invertebrate or fungal attackers. In many habitats, *Mimosa pigra* has the ability to completely dominate a site, forming impenetrable, monospecific shrub stands up to 6 m tall.

Rates and pattern of invasion have been best documented for northern Australia. Movement away from the entry point in Darwin has taken more than 50 years, but spread since the 1970s has been rapid. Within a river system stands expand on average at the rate of 76 m yr⁻¹, resulting in a doubling time of 1.4 years. Peripheral expansion is fastest following higher than average rainfall during the wet season, suggesting the importance of water for both the dispersal of seeds (in the wet season) and the survival of seedlings (through the dry season). An example of this spectacular rate of local spread has been given for a site of known history where a stand grew from a few individuals to one covering an area of 60,000 ha in approximately 10 years. At a larger scale, the doubling time for new infestations is slower (6.7 years), due to habitat heterogeneity.

The role of introduced grazing animals in the invasion of *Mimosa pigra* is debated. In northern Australia, the feral asiatic water buffalo (*Bubalus bubalis*) was thought by pastoralists to limit the spread of *Mimosa*, because of its conspicuous expansion since the lowering of buffalo densities as part of a disease (brucellosis and tuberculosis) eradication program in the mid-1980s. However, in the two decades prior to this, both buffalo numbers and *Mimosa pigra* infestations increased in parallel, and recent evidence shows that the most readily

invaded habitats (wetland margins) are those most disturbed by large grazers, lacking tall trees, and with long periods of inundation.

Mimosa pigra drastically alters the composition and use of natural ecosystems. In Australia, it has supplanted native sedge land and grassland communities on flood plains and has invaded and displaced adjoining *Melaleuca*, *Eucalyptus*, and *Pandanus* woodland. The tall cover of *Mimosa* decreases native biodiversity and threatens the rich wildlife associated with open habitats. Ecosystem modifications caused by *Mimosa pigra* have reduced native resources accessible for traditional aboriginal use, pastoral grazing, and ecotourism ventures. The enormous scale and potential level of impact of *Mimosa pigra* is highlighted by estimates provided for Kakadu National Park (13,000 km²), a World Heritage Area containing a full range of natural habitats within 150 km of the coast. Over 80% of the park is vulnerable to invasion (29% seasonally flooded areas susceptible to complete displacement; 54% largely open forest and woodland, which could have *Mimosa pigra* as a common element). Only 17% (extreme edaphic sites) of the area appears beyond the ecological tolerance of *Mimosa*.

The management and control of *Mimosa pigra* in natural ecosystems present a major challenge. It is susceptible to mechanical removal, herbicides, fire, and competition from grasses, and all are being used, often in combination, to eradicate new infestations and control the expansion in Australia. However, to be effective, treatments need to be repeated at regular intervals for at least a decade due to resprouting from damaged stumps and recolonization via the seed bank (10⁴ seeds m²). Currently an extensive biological control program is being undertaken testing several insects and pathogens.

Pinus Pinaster (Pinaceae)

Members of the Pinaceae, notably *Abies*, *Larix*, *Picea*, and *Pinus*, are the most widely planted exotic tree species in the world and form the basis of production forestry in many countries. The evolutionary history of the family is centered on the northern hemisphere, but in the 20th century the geographic range of northern conifer species has been greatly extended to many southern hemisphere regions where they have been evaluated and used for forestry, amenity planting, reforestation, and erosion control. Translocation of *Pinus* species in particular has occurred on a grand scale, initiated by European settlers. In South Africa, for example, more than 80 of the 111 species worldwide have been planted since the late 17th century. Outside their native range, at least 20 species have established away from plantations into adjoining grassland, shrub land, and woodland communities. Because of their size, growth rate, and fecundity, pines have been responsible for generating widespread concern internationally about the potential impacts of introduced plant species. *Pinus pinaster* (cluster pine, maritime pine), native to the Mediterranean region, typifies the invasion history and types of impacts that pines can have, particularly in nonforest ecosystems.

Naturally occurring in the Mediterranean Basin from Portugal to Algeria, *Pinus pinaster* is a two-needled, tall (40 m),

Figure 10 Thousands of hectares of *Pinus pinaster*, after 100 years of spread in the Riviersonderend Mountains near Genadendal, Western Cape Province, South Africa. Photo: David Richardson.

open-canopied pine species frequently growing on sandy soils and dunes among oaks and heathland shrubs at low to moderate altitudes, but extending up to 1500 m. Valued for resin potential and for erosion control, *Pinus pinaster* has been planted widely in South America, Australasia, and South Africa, where it has invaded a range of natural and modified communities. Plantations have also been established in Europe, within its native range, and these are similarly spreading.

The ecology and spread of *Pinus pinaster* has been best documented in South Africa, where it was introduced in the late 17th century and subsequently widely planted for timber and drift sand stabilization. Two hundred years later *Pinus pinaster* has invaded 3256 km² of natural vegetation (Figure 10) and is one of several pine species (*Pinus halepensis*, *Pinus radiata*) that threatens the conservation of one of world's biodiversity gems, the fynbos biome. Extending for 71,337 km² in the Cape Floristic region, the fynbos biome comprises complex, species-rich (7300 vascular plants), fire-adapted, mainly shrub-dominated ecosystems with a high proportion (80%) of local endemics. The pines have spread peripherally around source plantations and also via long-distance (up to 5 km) wind dispersed seed. These outliers gradually coalesce to form extensive stands in which *Pinus pinaster* is more than 25% of the cover. On the Cape Peninsula near Cape Town, pines are the most common introduced plant species in 10 of the 15 vegetation types represented at the Cape, with *Pinus pinaster* dominant over 560 ha or 1.1% of the total area.

The success of *Pinus pinaster* and other invading pines is due to a combination of factors including particular species traits, natural features of the fynbos, and various human activities. Weedy pines, in this ecological context, are distinguished from nonspreading species by their resilience to fire (e.g., short period to reproductive maturity, above-average levels of serotiny) and dispersibility (small seeds with low seed-wing loading). The fynbos vegetation is fire prone, and natural fires at intervals of a decade or more maintain a mosaic of shrub land and gully forest, depending on the timing and intensity of the burn. Fire frequencies have increased with greater human activity in the region, creating ideal invasion opportunities for fire-adapted, fast-growing, and early-

maturing introduced species. Plants derived from abundant seed sources blown in from established plantations have penetrated the fynbos after fire, increasing (by up to 300%) the available flammable biomass, and gradually consolidating dominance with successive fire cycles.

In the absence of management, *Pinus pinaster* and the other pines would eventually transform much of the diverse fynbos vegetation into an introduced conifer forest. The shift in life-form dominance threatens some rare native plant species and will suppress many other light-demanding plants, although they may provide new habitats for arboreal native birds. The large increase in stand biomass caused by pine invasion has increased interception and transpirational losses resulting in decreased stream flow (by between 30 and 70%) for human consumption from pine-dominated catchments. The pines have induced a new vegetation structure and system, mainly as a result of increasing the intensity of burning, and few native species can cope with the new disturbance regime.

Management for the conservation of the fynbos biome must include controlling the invasive pines. Where plantations adjoin watersheds, massive clearing operations are financially justifiable in view of the major impact of invading pines on water delivery from catchments.

Options currently being undertaken involve prescribed burning at intervals of 12 to 15 years, in conjunction with mechanical clearing of pine stands and outliers. Pines are felled 12 to 18 months before burning to allow time for seeds to be released from serotinous cones, and seedlings to establish. These are subsequently killed by the fire. Biological control approaches using seed-attacking insects are being explored for *Pinus pinaster* and *Pinus halepensis* as long-term solutions for effectively managing pines in fynbos landscapes.

Predicting and Evaluating Impacts

Most countries want to limit the influx of potentially invasive plant species and to identify and contain those that already exist within the large reservoir of introduced plants confined to cultivated areas. The commonest approach to improving biosecurity at the border and enabling recognition of new weeds at a very early stage of invasion when control is both cost-effective and practicable is to apply some form of weed risk assessment analyses. These invariably include evaluations of potential impact on human activities (e.g., agricultural production, animal health) and natural environments. Information is commonly derived from weed databases on the behavior of the plant species elsewhere in the world or from assumptions about the relation between plant traits and species impact. In general, features that enable a species to either capture or produce an important resource will have the greatest effect on plant community composition and structure and will initiate major changes in ecosystem processes and functions. Key traits vary depending on the local environment and the type of land management, but those that either assist species to acquire an unequal share of key resources (e.g., relative growth rate, height), foster new disturbance regimes (e.g., fire), enhance local persistence (e.g., long-lived soil seed bank), or create a major increase in resource availability (e.g., nitrogen-fixing rhizobia) are likely to be the most important

in any risk analysis. However, stochastic processes (e.g., change in land use), complexity of multiple interactions in natural ecosystems (e.g., presence of seed dispersers), and the increasing prevalence of introduced plant species lacking a weed history elsewhere collectively contribute to making weed impact prediction a major challenge. Methods for evaluating comparative benefits (e.g., food source for humans and native animals, erosion control) and costs (e.g., loss of crop production, reduced native biodiversity) of introduced invasive weed species are only slowly emerging due to difficulties in assessing qualitative and quantitative elements of these categories in simple economic terms.

Glossary

Alpha landscape diversity Number and dominance of patch types within a landscape.

Corridor Strip of land or water that differs from the adjacent landscape on both sides.

Gamma landscape diversity Total number of patch types contained within a geographic region.

Landscape Spatially heterogeneous area composed of a mosaic of interacting components (patches, corridors, and area of matrix).

Matrix Background landform, habitat, or ecosystem in a landscape, characterized by extensive area, high connectivity, and major control over landscape dynamics.

Patch Area that is relatively homogeneous with respect to the characteristics being examined, and that differs from its surroundings.

Region Large geographic area that contains more than one landscape.

Introduction

While biodiversity is usually considered at the species level, maintenance of biodiversity requires management at higher levels of organization, particularly at the landscape scale. It is difficult to manage for each threatened species individually. Alternatively, management can focus on the ecosystems that contain these species and on the landscapes in which ecosystems are found. The relatively new discipline of landscape ecology provides an insight into both landscape diversity and species diversity, and suggests a theoretical and practical basis for conservation planning.

There are three basic characteristics of landscapes that affect their diversity: structure, function, and dynamics. Structure is the most well-understood element of landscapes. It is also the most obvious – nearly any aerial view will show a mixture of different landforms, habitats, or vegetation types. The patch is the basic unit of landscape structure. The characteristics of patches and the spatial relationships among patches are important components of landscapes. The distributions of energy, materials, and species among patches differing in size, shape, abundance, and configuration are particularly important to patterns in diversity at the landscape scale. The other two elements of landscapes go beyond a description of spatial heterogeneity. Function is concerned with interactions among the spatial elements of a landscape, including flows of energy, materials, and species among patches. Landscape dynamics includes characteristics of both structure and function to examine changes in pattern and process over time. The conservation and management of biodiversity require an understanding of all three elements, including the effects of human activities on the system. This article discusses each element in turn, and also considers the underlying determinants of landscape structure, including environmental heterogeneity and disturbance patterns. The authors then

discuss classical and current issues in biodiversity management and conclude with a case study of landscape diversity at the Sevilleta National Wildlife Refuge Long-Term Ecological Research site in central New Mexico, US.

It is essential to keep the concept of scale in mind when considering landscape diversity. Spatial scale has two elements: grain and extent. Grain is the minimum resolution sampled, usually the cell size or the quadrat size for ecological studies. The extent is the domain of the study, which is typically the size of the study area. Ecological processes often have characteristic spatial and temporal scales. This means that the grain and extent of sampling in both space and time may strongly affect the results of a study. For example, as quadrat size (grain) increases, species richness may increase, and yet the diversity of patch types within a landscape may decrease since fewer large quadrats can be found within a given area (**Figure 1(a)**). As landscape size (extent) increases, more species and more patches of a constant size may be found that would increase both species and landscape diversity (**Figure 1(b)**).

Description of Landscape Structure

Landscape structure can be most easily described at two hierarchical spatial levels, both of which are relevant to landscape diversity as well as to species diversity. At the lower level, the focus is on the attributes of individual patches, particularly size and shape. Description at the higher spatial level is concerned with the composition and pattern of the entire landscape and its mosaic of patches. The ability to quantify landscape structure at both levels allows the comparison of different landscapes. More importantly, interactions between landscape structure and function have implications for both species and landscape diversity.

Figure 1 Landscape grain and extent: (a) as the grain or the quadrat size of a landscape increases, yet the extent remains the same, the diversity of patch types decreases since fewer quadrats can be found in the same area; (b) as landscape extent or size increases, more species and more patch types of the same size can be found that result in higher landscape diversity.

Patch Description

A patch is a relatively homogeneous nonlinear area that differs from its surroundings. The definition and identification of individual patches and their boundaries are important steps in characterizing the structure of a landscape. In some systems, boundaries may be easily identified, such as between patches of agricultural field and adjacent woodland in human-dominated systems. In many cases, however, the boundary is not so clear, and patches are more difficult to delineate. Most methods of patch identification combine qualitative and quantitative approaches. A subjective determination of how different two areas must be in order for them to be considered separate patches is often needed. A number of quantitative techniques have been developed to group similar cells into homogeneous patches or to identify repeating patterns across a landscape (Turner and Gardner, 1990). Approaches such as blocking techniques, spectral analysis, and nearest-neighbor analysis are commonly used. Other techniques rely on the detection of edges or boundaries rather than identifying patches directly. These methods include moving window analysis and image analysis to characterize landscapes with sharp transitions (Cornelius and Reynolds, 1991).

Patch identification provides an excellent example of the importance of the spatial scale of the observer. From inside a forest, clumps of trees and grass-dominated openings appear to be separate patches with different vegetation and resource availability. From an aerial view, the entire forest appears to be a single patch. This illustrates the importance of the selection of spatial scale based on study objectives before the determination of patches and their edges.

Once the patches in a landscape have been identified, there are many ways to describe and quantify them (Riitters *et al.*, 1995). Only patch size and shape will be discussed here, since the relevance of these two attributes for species diversity is the most well understood. The relationship between patch size

Figure 2 Species-area curve showing the increase in species number with increasing patch size tending toward a regional limit.

and species richness goes beyond the familiar species-area curve (Figure 2). Although the number of species present in a patch tends to increase with patch size up to a certain limit, the kinds of species found also tend to vary with size. Two general types of species can be distinguished. Interior species are found primarily in the interior of large patches. These species often have very specific habitat requirements and are relatively rare. Migratory songbirds that are particularly sensitive to patch size and adversely affected by habitat fragmentation are interior species. In contrast, edge species are found near the edges of large patches and throughout small patches that consist mostly of edge habitats. Edge species are commonly occurring generalists that can use various habitat types, and are often introduced species. Because small patches consist mostly of edge with little interior area, they often have the highest species densities, but contain few or no rare species. Large patches, however, are mostly interior area with lower species densities per unit area, but they contain more rare species and a higher total number of species.

In an important study of tropical deforestation in the Amazon rain forest, species in patches of various sizes were compared to evaluate the importance of patch size to species number (Lovejoy *et al.*, 1984, 1986). Large patches were richest in species and small patches were found to contain only edge conditions. Patch size had important effects on different species, including trees, insects, birds, and mammals, which were noticeable in a short time. This study is one of the few in which patch size was experimentally manipulated to allow comparison with pretreatment conditions as well as control patches.

A simple measure of patch shape is the perimeter: area ratio. This measure is often standardized so that the most compact possible form, either a square or a circle, is equal to 1. More complex shapes have increasingly higher numbers. Another common index of shape complexity is the fractal dimension, which is also derived from the perimeter and area of a patch. The fractal dimension of a patch is between 1 and 2; a simple shape will have a lower fractal dimension than a more complex shape. Figure 3 illustrates the amount of interior area available in patches of different shapes. Both patches have an area of 25, but the perimeter of shape a is 20, while the perimeter of shape b is 32. Using a scaled perimeter: area ratio, a has a value of 1 and b has a value of 1.6. Assuming that

Figure 3 (a) A simple shape and (b) a more complex shape of equal area. The interior area is shaded.

interior area is at least 1 unit from any patch edge, *a* has an interior area of 9, but *b* has an interior area of only 2. Thus, *a* is more compact and less convoluted than *b*, where more of the area is closer to its edge and can interact with the area surrounding the patch. This suggests that the overall flow of species and resources between *b* and its surroundings is higher than that between *a* and its surroundings. It is also expected that *a* would have higher richness of interior species than *b*, which would have higher richness of edge species.

Landscape Description

At the landscape level, there are two basic components of structure: composition and pattern. Composition refers to the parts (i.e., patch types) that make up the landscape and pattern refers to how these patches are arranged. Although these two components are conceptually different, in practice, they are often related. For example, the pattern of agricultural fields on a landscape is likely to be different from the pattern of undisturbed woodland.

Landscape composition can be measured in ways analogous to measurements of species composition (Romme, 1982). The most straightforward approach is landscape richness or the number of different patch types in a landscape. Another approach includes the relative abundance or dominance of different patch types along with richness. These landscape indices were derived from information theory and are closely related to species diversity measures, such as the Shannon–Wiener and Simpson indices, which are used to describe alpha species diversity (Turner, 1989; Huston, 1994). Using one of these indices, a landscape containing many small patches of different types would have a higher diversity value than a landscape consisting of one large patch and several smaller patches, even if the total number of patches is the same for both landscapes. Landscape measures of richness and evenness were used in a study conducted in different patch types in Yellowstone National Park (Romme, 1982). Changes in landscape diversity through time were related to fire frequency and were hypothesized to have important effects on species diversity as well as wildlife habitat (Romme and Knight, 1982).

Measurements of landscape diversity are analogous to common measurements of species diversity (Whittaker, 1960, 1972). Alpha species diversity is a measurement of species richness (number) and evenness (dominance or distribution)

within a patch. Similarly, alpha landscape diversity is a measure of the number of patch types in a region (O'Neill *et al.*, 1988). Large-scale species diversity is called gamma diversity. Gamma landscape diversity of ecosystems is sometimes called ecodiversity (Rowe, 1992; Lapin and Barnes, 1995). The third form of species diversity, beta diversity, describes species turnover along a gradient. Beta diversity has no analog at the landscape level, but is sometimes estimated as gamma diversity/alpha diversity, which yields an average regional beta diversity.

Because different patch types provide different habitats and species compositions, one might expect that the total number of species in a landscape would increase as landscape richness increases. This idea was supported by a study that compared plant species richness in Rhode Island Audubon refuges varying in terrain and soil properties (geomorphological measures) (Nichols *et al.*, 1998). In a related study of one landscape, the diversity of trees and shrubs was higher on plots with the greatest geomorphological heterogeneity, indicating an important link between landscape diversity and species diversity (Burnett *et al.*, 1998). Although this simple relationship between landscape and species diversity is generally true, the interactions between landscape composition and species diversity are more complex, in part because of species preferences to edge or interior types of habitats. The species found in a diverse landscape with many small patches are mostly edge species. Interior species are found only in landscapes with large patches, even though these landscapes have a lower diversity. The total number of interior species increases with the number of large patches on a landscape, similar to the species–area relationship in Figure 2. Thus, the type of species that increases with increasing landscape diversity depends on the change in the size and configuration of patches within the landscape.

Landscape pattern, or the spatial arrangement of patches, can be measured in a number of ways, some of which are extensions of the patch-level metrics already discussed. These measures focus on patch abundance without regard to location in the landscape. The distribution of patch sizes can be determined within a landscape and used as information in the management of habitat patches for species that are sensitive to patch size or spatial arrangement, such as the spotted owl in the Pacific Northwest. The effects of forest clear-cutting on changes in patch structure and implications for interior and edge species provide another example of the importance of these measures. Shape complexities and boundaries can also

be scaled up from the patch to the landscape level using the fractal dimension and perimeter: area ratio (Milne, 1988).

The second type of measurement for landscape pattern explicitly considers the location of patches relative to each other and includes patch abundance as well. Dispersion indicates the tendency of patches of one type to be distributed either uniformly, randomly, or aggregated. Contagion describes the tendency of patches of two different types to be near each other. Connectedness can be quantified using nearest-neighbor probabilities that reflect the degree of fragmentation in the landscape. All three of these indices have implications for the flow of species and resources between patches of the same and different types, and thus have important effects on species diversity. The effects of patch characteristics and landscape context on species richness can even be seen in heavily managed agricultural communities (Goslee and Sanderson, 2010).

Two additional structural elements other than patches may be recognized in many landscapes. The second element is the matrix or the background land-form, habitat, or ecosystem in a landscape. The matrix is characterized by extensive cover, high connectivity, and major control over landscape dynamics. Forest patches contained within a matrix of subdivisions are functionally very different from forest patches surrounded by agricultural land. Corridors, strips that differ from the adjacent landscape on both sides, are the third element of landscapes. Corridors are usually linear and always highly connected; stream networks and roadways are common examples. Corridors may also connect larger patches of a similar type, such as a stream flowing between two lakes.

The patch-matrix-corridor model of landscape structure is illustrated in Figure 4. Corridors may be particularly important for preserving species diversity by allowing movements of species across diverse landscapes. Corridors can also adversely affect species diversity by allowing nonnative or exotic species to invade and reduce the number of native species in an area. An example is the extensive spread of cheatgrass, an annual introduced to North America in shipments of grain from Asia

and Europe in the 1880s (Mack, 1981). Movement of cheatgrass seed along railroad and cattle trail corridors in the early 1900s spread this grass throughout much of the northwestern US, resulting in changes in species composition and dominance as well as losses of diversity.

Controls on Landscape Diversity

Heterogeneity or diversity of landscape structure arises from a number of factors. Patches can be produced through biotic or abiotic causes, including natural- or human-caused disturbance, fragmentation, regeneration, and persistent differences in environmental resources. Once a patch is formed, environmental conditions or interactions among organisms may change through time, leading to successional dynamics on the patch. A landscape consisting of patches in various successional stages is called a “shifting mosaic” (Bormann and Likens, 1979). The spatial pattern of patch formation and the changes within patches are collectively called “patch dynamics” (Pickett and White, 1985). The patch dynamic mosaic is part of the broader landscape transformation that includes changes in corridors and the matrix as well as in the dynamics of species and ecosystem processes. These dynamics are discussed in Section Landscape Dynamics.

Biotic causes of patch generation include the local dispersal of seeds into a landscape, such as by an invasive weed, and the spatial segregation of populations or communities as a result of competition. Spatial structure can also be generated by differences between species in their dispersal abilities and rates of mortality. Naturally occurring and human-created disturbances are common causes of patch formation. A wide variety of natural disturbances are possible, including mud slides, avalanches, windstorms, ice storms, herbivore outbreaks, animal grazing, trampling, and digging, as well as fire. Mounds produced by badger digging activities in tallgrass prairie are an example of patch-producing disturbances that have important influences on patch structure as well as species

Figure 4 A matrix of agricultural land with patches of two types: woodlots and a farm pond. Windbreaks of trees act as corridors connecting the woodlots. Hedgerows and wooded windbreaks often create travel routes for wildlife.

diversity (Platt, 1975). Human activities, such as forest cutting, altered fire regimes, cultivation, urban development, introduction of pests, and strip mining for surface coal and minerals, also produce disturbance patches. Many landscapes are influenced by both natural- and human-caused disturbances, and distinguishing the separate effects on landscape diversity can be difficult. In a recent study, pollen and charcoal were collected from small lakes in Massachusetts to reconstruct long-term vegetation dynamics as related to disturbance history (Fuller *et al.*, 1998). This reconstruction over the past 1000 years included the period of time before European settlement, when the primary disturbances were fire and wind. Landscape patterns in forest composition following settlement by Europeans were largely influenced by clearing of forests for agricultural purposes and timber. These researchers found that the past history of disturbance as a result of settlement has persistent effects on current landscape patterns.

Landscape fragmentation is closely related to disturbance. Many forms of disturbance effectively break up large patches into smaller pieces. Decreases in patch size, connections between patches, and total interior area as a result of fragmentation have important implications for species and landscape diversity. As landscapes become more fragmented, patch diversity increases, with subsequent increases in edge species, exotic species, and generalists. Richness in interior species tends to decrease. Fragmentation of landscapes by human activities is considered a major threat to biodiversity worldwide (Saunders *et al.*, 1991; Bierregaard *et al.*, 1992). A major focus of the field of conservation biology is the design of nature reserves to maximize the likelihood of species existence and to minimize the loss of species to extinction. These processes are discussed in the Section, Biodiversity Planning at the Landscape Level.

Another cause of patch formation is environmental heterogeneity, which refers to variation in soils, topography, and other landform features. This variation in the physical environment leads to a heterogeneous or a patchy spatial distribution of resources, including water, nutrients, and light. Plant species found in a resource patch can differ from species in other patches containing different levels of resources. The importance of spatial heterogeneity to species diversity has been well documented, and is most closely related to beta species diversity. These ideas have also been extended to landscape diversity, where studies have linked measures of alpha and beta species diversity with landscape diversity (Romme, 1982; Lapin and Barnes, 1995). Large-scale gradients in landscape diversity can also be related to broad-scale patterns in the environment. For example, spatial variation in climate, topography, and soils was found to be strongly related to latitudinal gradients in the richness of land cover types across the continental US (Wickham *et al.*, 1995).

Landscape Function

Interactions among the spatial elements of a landscape are the major components of landscape function. These flows of energy, materials, and species among patches, or among patches, corridors, and the surrounding matrix, are at least as important to the maintenance of diversity as patch size and configuration. However, these flows have not been as well studied

as landscape structure. An example of flows among different patch types is the dispersal of seeds from forest patches into clear-cuts, which has important effects on vegetation dynamics in these open areas. Boundaries or edges between patches or between patches and the mosaic often control the strength of interactions or the amount and kinds of materials that can move between the landscape elements. Because of the importance of edges, boundaries of patches can have very different characteristics than interiors. For example, edges of recently disturbed tropical forest patches have greater tree mortality and increased recruitment of early-successional species compared with interior areas (Bierregaard *et al.*, 1992). Boundaries can also change location through time, with resulting effects on landscape structure. In contrast to boundaries, where movement is generally restricted, corridors linking similar landscape elements tend to improve or enhance flows. Movements of organisms through corridors become increasingly important as the landscape becomes more fragmented (Saunders and Hobbs, 1991).

Studies have also examined the influences of landscape structure on flows of organisms and materials. Patchy environments in Yellowstone National Park were found to be more resistant to large fires than were homogeneous landscapes, and after burning, they had a greater ability to maintain water quality (Knight and Wallace, 1989). Historical migration patterns of wild ungulates, such as wildebeest in the Serengeti of Africa and bison in North America, were mostly related to patterns of rainfall that were spatially variable both locally and regionally (reviewed in Frank *et al.*, 1998). Changes in landscape structure through fencing and urbanization have restricted migration patterns and resulted in animal overabundance and overgrazing in wildlife preserves. Biogeochemical fluxes, such as CO₂ and various forms of nitrogen, can also be affected by patches within a mosaic structure created by human land use. Gene flow and metapopulation dynamics are other examples of processes that respond to spatial structure in a landscape. A population that is spatially subdivided into patches that are connected through dispersal is called a metapopulation. Movement of individuals between subpopulations can reduce the risk of local extinction of species within small isolated patches.

Landscape Dynamics

Landscape structure and function can change for many reasons and in many ways. Changes can occur over very small or very large areas and over short or long time spans. The gap caused by a single tree falling in the forest during a storm is small and temporary, while an entire forest may be leveled by a hurricane and may take decades to centuries to recover.

Vulnerability or sensitivity to change varies from landscape to landscape. This vulnerability (or, conversely, stability) is traditionally divided into two components: resistance and resilience. Resistance is the ability of a patch or a landscape to remain unaffected by a disturbance. A grassland is much more resistant to wind damage than a forest, since grasses can bend with the wind without breaking. Resilience is the ability of a patch or a landscape to recover after a disturbance. Temperate forests recover after clearing much more quickly than tropical

forests (which may never recover) owing to differences in soil depth and fertility.

Change in a patch or a landscape can be caused by any number of factors. Some of these are intrinsic to the population being studied, including recruitment, growth, mortality, and spread or migration, which can lead to invasions or extinctions as well as changes in patch boundaries. Other causes are extrinsic to the ecosystem and are imposed by outside forces, such as climate change and disturbance events. Human transformations of the landscape include deforestation and reforestation, urbanization, corridor construction, and agricultural conversion. The effects of consumers, pathogens, and especially humans can be considered either intrinsic or extrinsic depending on the particular point of view. The potential causes of change may be interrelated in complex ways. A drought may make a forest more vulnerable to pathogens or a new clearing may increase the vulnerability of adjacent trees to windthrow.

Changes in landscape structure can have several spatial and temporal forms. Patches can shrink or expand, or be lost entirely. Successional dynamics on patches can lead to a shifting mosaic of patch types through time. Species interactions with other species and with their environment, as well as dispersal of new species into patches, are primary determinants of the regrowth of plants on these successional patches. Changes in patch size and shape can occur along edges, such as the clearing of forest, to increase the size of a cultivated field (**Figure 5(a)**). A new patch type may spread outward from a corridor (**Figure 5(b)**). For example, housing developments often spread from the course of new roads. Alternatively, a patch type may spread out from a nucleus that could be a remnant of a previous vegetation type or an introduction site for a new patch type (**Figure 5(c)**). Some changes are nearly instantaneous and occur over very short periods of time, such as the effect of fire. Other changes occur slowly and take a longer period of time to develop, such as suburbanization and desertification (Peters *et al.*, 2004).

Patch configuration on a landscape can also change. Patches can become perforated by other patch types, and large patches can be fragmented into several smaller patches. Landscape fragmentation, particularly in the tropics, is having severe effects on species biodiversity. Some of the potential consequences of fragmentation include the loss of patch types and their characteristic species, decreased connectivity with its repercussions for species movements, and decreased interior area. The biggest consequence for species diversity is the associated loss of interior species and the increase of generalist or edge species.

Landscape-level dynamics are often studied with ecological models since the temporal scales of interest are often greater than the human life span, and experiments are difficult to perform at large spatial scales. There are four general classes of models that are used to predict landscape dynamics: transition probability models, individual-based models, ecosystem process models, and biogeographic models (Peters, 2011). Transition process models are useful when the factors causing landscape change are not represented mechanistically. For example, assume that a landscape with three patch types was sampled twice, before and after an event. A table can be constructed showing the percentage of each patch type that remained the same or that was transformed into a different patch type in this hypothetical landscape (**Table 1**). Each row shows the fate of a particular patch type. Over a single time step, 60% of the forest land remained forested, 25% was converted to agricultural uses, and 15% was developed. These transition probabilities can be used to extrapolate into the future by individual time steps. **Figure 6** shows the projected change over 25 time steps if this original landscape had 50 units of forest, 25 units of agriculture, and 10 units of developed land. This landscape will stabilize with a high proportion of developed land and a very small forest area. Transition analyses are very simple to conduct and can be useful for examining the effects of various probabilities and initial conditions. In the simple form presented here, no

Figure 5 Three common patterns of landscape change. Arrows indicate the direction of spread. (a) An edge where agricultural land encroaches on forest along a field boundary. (b) A corridor where development spreads outward from a new road. (c) A point where reforestation proceeds outward from an isolated forest patch.

allowance was made for variations in the rate of change and no specific spatial component was included.

Each cell shows the percentage of the landscape area that changed from the patch type in that row to the patch type in that column over a single time step. For example, 25% of the original forest land was cleared for agriculture and 15% was developed. **Figure 6** shows this projected change over 25 time steps.

Individual-based simulation models are useful when information is known about the mechanisms underlying changes in landscape structure. These models incorporate life-history traits of individuals and the mechanisms by which they interact with their environment to predict landscape-level dynamics (e.g., [Peters, 2002](#)). Landscapes are simulated by linking plots together in a grid or a transect. Plots are spatially interactive through processes such as seed dispersal. Spatially interactive individual-based models can represent a variety of environmental conditions, including differences in soil properties, climate, and disturbance regime ([Coffin and Lauenroth, 1994](#)). These models are most commonly used for evaluating changes in the diversity of groups of similar species (i.e., functional types) rather than species diversity ([Paruelo et al., 2008](#)).

A third class of models simulates ecological processes, including rates of nutrient cycling, water balance, and primary

production (e.g., CENTURY and DayCent: [Parton et al., 1987, 1998](#)). These models have been linked with geographic information systems (GIS) to simulate large regions. The effects of climate, soil texture, and management on soil organic carbon dynamics were simulated for the central grasslands of the US ([Burke et al., 1991](#)). Across this large region, soil organic carbon increased with precipitation and decreased with temperature and percentage sand content. Biogeographic models are a fourth class of models that can be used to investigate vegetation responses to environmental heterogeneity. These models incorporate large-scale variations in climate and soils, as well as water and energy constraints on plant growth, to simulate continental and global patterns in vegetation. Biogeographic models are most useful for simulating responses of plant functional types at large spatial scales, to either equilibrium or transient environmental conditions ([Prentice et al., 1992](#); [Neilson and Drapek, 1998](#)). These models can incorporate landscape-scale processes or connections among patches, such as spread of wildfire ([Lenihan et al., 2008](#)).

Although each of these types of models has traditionally been used independently, the linking of different models together has considerable potential for addressing issues related to landscape diversity. Because of important feedbacks between species and rates of ecosystem processes ([Schulze and Mooney, 1994](#)), linking a spatially interactive individual-based model with an ecosystem model can simulate the dynamics of landscape structure and function as well as changes in functional group diversity ([Epstein et al., 1999](#)). A nonspatial individual-based model linked with a nutrient cycling model was also used to examine the importance of soil heterogeneity to forest responses to global climate change ([Pastor and Post, 1988](#)). The incorporation of landscape-scale flows of water, carbon, and nutrients into a spatially interactive individual-based model is an important research area

Table 1 Transition matrix for a hypothetical landscape with three land-use types

	Forest	Agriculture	Developed
Forest	60	25	15
Agriculture	10	75	15
Developed	0	2	98

Figure 6 Transition matrix analysis of a hypothetical landscape with three patch types of differing abundance: forest, 50 units; agriculture, 25 units; and developed, 10 units. Transition probabilities are shown in **Table 1**.

for predicting landscape diversity dynamics that includes individual species responses (Peters, 2011). Linkages between biogeochemical and biogeographic models are another area of application to landscape diversity, especially if species or plant functional types are resolved and landscape-scale processes, such as disturbance regime, are included (Lenihan *et al.*, 2008).

Biodiversity Planning at the Landscape Level

To preserve species diversity most effectively, management plans must preserve the habitats and landscape structures needed by the target species, rather than simply preserving the species in isolation from the larger, potentially changing the environment. Management practices aimed directly at a particular species run the risk of losing ecosystem functions that might actually be crucial for the target species, but that were unknown when the management plan was created. Furthermore, maximizing benefits for one species may threaten others. The ideal is to preserve overall ecosystem health, including species diversity. Unfortunately, this is easier said than done. Much of the effort of conservation biologists has been directed toward learning how to manage ecosystems, at both theoretical and practical levels.

One of the classic debates in conservation biology centers around the best reserve design. If limited resources are available to purchase land, is it better to establish one large reserve or a few smaller ones? This has become such a well-known and controversial issue that it has its own acronym: single large or several small (SLOSS). A large reserve provides the most potential habitat for interior species, which are usually the ones most in need of protection. However, a single reserve is vulnerable to all sorts of disasters. If a major hurricane or a pathogen hits that reserve, there are no other reserves to take its place. The establishment of several smaller reserves minimizes the risk of losing everything at the same time. However, a minimum size is needed to sustain populations of interior species as well as to preserve the characteristic species diversity and species composition of the ecosystem. Furthermore, reserves do not operate like isolated islands; thus, connections between reserves and the surrounding habitats are also important.

A related concept involved in determining the optimum size of a nature reserve is the minimum dynamic area (Pickett and Thompson, 1978). Assuming that the disturbance regime of an area is known, the frequency, areal extent, and recovery time can be used to determine the smallest reserve area in which there will always be some mature patch types to provide a species source for the rest of the area as it recovers from disturbance. If a patch is smaller than this minimum dynamic area, it will likely be eliminated through time simply from natural disturbances.

Given the large number of species on the planet, it is impossible, or at best impractical, to manage for every one of them. Instead, conservation biologists are now trying to identify ways to simplify the task of landscape-level management. The most promising methods identify one or a few important species and focus on their management. One tactic is to manage keystone species, those on which important

ecosystem functions or other species depend. Another approach is to target umbrella species, those with large ranges or broad habitat requirements. Managing for these species will automatically save many other species with smaller or less inclusive requirements. A similar method identifies a set of focal species, each of which is sensitive to a particular aspect of landscape structure or function. One of the focal species might be especially vulnerable to habitat fragmentation, whereas another might require a high level of connectivity. The protection of this set of sensitive species provides the management goals. When the requirements of the sensitive species are met, other species will likely be provided for as well.

Case Study: Sevilleta National Wildlife Refuge

The Sevilleta National Wildlife Refuge (SNWR; 34.5° N, 106.9° W), located approximately 75 km south of Albuquerque, New Mexico, provides an excellent example of landscape diversity and its relationship with species diversity. This 100,000 ha wildlife refuge was established in 1973 and is currently managed by the US Fish and Wildlife Service. The refuge is also a Long-Term Ecological Research site funded by the U.S. National Science Foundation. The climate at the SNWR is semiarid to arid, with low amounts of precipitation and high temperatures during the April to October growing season. The mean annual precipitation over the past 65 years was 23.4 cm. (SD = 70.4 cm) and the average annual temperature was 14.1 °C (SD = 0.7 °C).

The SNWR is uniquely located at the ecotonal boundary between four major grassland-shrubland biomes found within the continental US (Peters *et al.*, 2006). Two of these biomes, shortgrass steppe ecosystems and Chihuahuan desert grasslands, form transition zones in the eastern part of the refuge (Figures 7(a) and (b)). Patches of variable size (<10 to >1000 m²) and shape occur and result in a high landscape diversity (Figure 7(b)). These patches can be differentiated into one of two patch types based on the cover of the dominant plant species (Gosz, 1995; Kröel-Dulay *et al.*, 2004). The vegetation of some patches consists mostly of blue grama (*Bouteloua gracilis*), the dominant species in shortgrass steppe ecosystems. A second patch type occurs, where the majority of cover is black grama (*Bouteloua eriopoda*), a dominant grass in Chihuahuan desert ecosystems. Species richness is similar for both patch types, although the canopy cover of plants is higher in black grama compared with blue grama patches (Peters *et al.*, 2006). A transect across the conceptual landscape shown in Figure 7(b) goes through each patch type as well as the matrix vegetation where similar cover of both species occurs (Figure 7(c)).

Within each patch, a smaller scale of heterogeneity also exists owing to disturbances associated with the burrowing activities of bannertail kangaroo rats (see Figure 7(b)). Mounds can be distinguished into one of three types based on plant species diversity as well as composition (Figure 8(a)). Active mounds are the site of frequent burrowing; thus, only plant species well adapted to disturbance can survive there (Fields *et al.*, 1999). Typically, this vegetation consists of small plants representing few species (Figure 8(b)). After mounds are abandoned and burrowing activities cease, more plant
